nal plate of the alveolar process. The maxillary sinus has been opened immediately over the roots of the first, second and third molars, showing, in this case, how thin the bone is between the roots of the teeth and the floor of the sinus. It is also very thin over the points of the roots of the cuspid and first and second bicuspsids. I wish to draw attention to the position of the infra-orbital foramen, which is usually

Figure 7.

described as the termination of the infra-orbital canal, which passes through the solid portion of the infra-

orbital ridge to the groove in the floor of the orbit. Several of the figures will show that this canal often passes diagonally through the sinus in the shape of

the passageway for the infra-orbital vessels and nerves, a distinct tube and not a passage channeled through the bone. The sinus in this case is seen extending into the infra-orbital ridge, forming what might be fitly termed an infra-orbital sinus. (I.O.S.)

The relations of the roots of the molars to the floor

Figure 8.

a tube—a fact I have not noticed described in any work on anatomy. In the lower jaw is shown the recurrent branch of the inferior dental canal opening at the mental foramen, together with other features of special interest to the oral surgeon.

Figure 9.

Figure 5 shows a vertical section made through the upper portion of the right superior maxillary bone. In the upper front portion of the antrum is shown

Figure 10.

of the antrum is an interesting feature of this section.

In consequence of the death and decomposition of the pulp of a molar tooth, there has been, first, irritation and a constructive periostitis upon the floor of the antrum, which has caused a thickening of the bone over the apex of the root. At a later period,

Figure 11.

suppurative inflammation has occurred, an abscess has formed and perforated the floor of the antrum.

Figure 6 shows the floor of the antrum extending between the roots of the molar teeth, a condition much more common among the white races than

among the negroes, according to my observation. Abscess upon the roots of such teeth may cause perforation of the floor of the antrum, and the extraction of a tooth would almost certainly be accompanied by fracture of the floor of the sinus. Note, also, that regarding the antrum as a cuboidal cavity, its exit is at its upper and inner angle. Note, also, the angle of the uncinate process. This is the usual

passed through the foramen of exit from the frontal sinus, the unobstructed path of which is directly into the antrum. I pointed out two years ago how common it was to find this condition, one in which effusions, or secretions, from the frontal sinus would find their way into the antrum.

Figure 9 is introduced to show the vertical septa, which frequently cross the antrum from side to side, springing from its floor, and dividing the lower por-

Figure 12.—Looking backward.

condition in all the skulls I have cut. You will see, therefore, that it is a mechanical impossibility to pass a probe from the anterior naris through the foramen of antral exit in normal bone.

Figure 7 is a tooth which has been drilled through while in the mouth, the operator supposing his drill was passing up the palatal root of the tooth, instead of which it passed through the base of the crown, the

Figure 13.—Looking forward.

pulp chamber, the alveolar process, and into the maxillary sinus. It will be observed that in extracting it a portion of the floor of the antrum has been brought away with the tooth. The patient was suffering, at the time of extracting, from empyema of the antrum.

Figure 8 is a section of a negro skull. Note the greater thickness of the floor of the antrum. The point of special interest in this specimen is the probe,

Figure 14.—Looking forward.

tion of the cavity into semi-chambers. Septa of two sizes are shown in the right and left sides. Note, also, how the development of the antrum has reduced the thickness of its walls to thin boundary layers. Note the projection of the bulla ethmoidalis upon one side; it is common to find a deviation of the nasal

Figure 13 a.

septum from that side in such cases, as may be seen in some of the following figures; adenoid growths are also common.

Figure 10 exhibits a condition occasionally met with, the floor of the antrum dipping inward, and partially under the floor of the nose; it will be noted, from the axis of the alveolar process, that in this case the sinus could be drained directly from the palatal aspect of the mouth.

Figure 11 exhibits an entire lack of symmetry between the nasal fossæ and the sinus of the right and left sides, the inferior meatus of one side being closed anteriorly by the deflected nasal septum.

Figure 15 b.

Figures 12 and 13 are from the same head. It will be noted that a line, or instrument, passed through the axis of the alveolar process of the right side would perforate the floor of the nostril, instead of the floor of the antrum.

Figure 14 is from the same subject, posterior to the

Figure 16.

other sections; the lack of symmetry of the antra is well marked, the more prominent side of alveolar process being associated with the larger antrum.

Figure 15 shows well the exit from the antrum at

its upper and inner portion, together with the direction of the hiatus semilunaris. Note, also, the section of the infra-orbital tube. The second figure of the cut shows the division of the sinus, which I have called the infra-orbital. At the right upper corner is the normal opening of the maxillary sinus, leading into the hiatus semilunaris, which is bounded below

Figure 17.

and to the inner side by the uncinate process, to outer side by the wall of the sinus, and above by the bulla ethmoidalis. This last named rounded projection contains the middle ethmoidal cells; they vary in size in different skulls, and very often in the same skull. I believe this structure to be an important factor in

Figure 18.

causing various diseases of this region, including those of the maxillary and frontal sinuses.

Figure 16 shows upper and lower views of a transverse section passing near the roof of the antra, where it is noted that the place of exit from the antra is in the roof.

Figure 17 shows by the probes passed through the

passages, the relative directions of the exits from the maxillary and the frontal sinuses.

Figure 18. Where there are two infundibula leading from the frontal sinus to the antrum, the probe passing upward into the frontal sinus passes through the infundibulum.

Figure 19.

Figure 19 shows the outer nasal walls, and the normal relation of the bulla ethmoidalis with the uncinate process, together with the nasal entrance to the maxillary sinus.

Figure 20 a.

Figure 20 shows abnormal perforation of the inner wall of the antrum. In consequence of the enlargement or distension of the chambers of the bulla ethmoidalis, there has been occlusion of the hiatus semi-

lunaris. Presumably the contents of the antrum have made for themselves an escape, by forming a false foramen. In Figure 20 a, the septum is in place. It will be seen that there is an opening in it, exposing to view the bulla and its ethmoidal cells. This absorption of the portion of the septum has been caused by pressure of the deflected septum, and the

Figure 20 b.

enlargement of the bulla ethmoidalis. Figure 20 b shows where the septum has been removed, exposing to view the two abnormal openings, and the loss of the greater portion of the middle turbinated bone by absorption through the pressure of the bulla down near the uncinate process.

Figure 21 is taken from the left side of the same

Figure 21 a.

skull. Figure 21 b has the middle turbinated bone in position, showing an abnormal opening. Figure 21 a has the middle turbinated bone cut loose and turned upward, exposing the bulla extending downward and closing the hiatus semilunaris, the passageway for the fluids from the frontal and maxillary sinuses, also from the anterior and middle ethmoidal

cells. This closure has been the cause of the abnormal opening from the maxillary sinus.

the axis of the molar teeth. The relation of the ends of the roots of these teeth with the floor of the antrum

Figure 21 b.

Figure 22.—Right.

Figure 23 b.

Figure 22.—Left.

Figure 24.

Figure 22. The right picture shows the outer wall of antrum removed, the section passing almost through

is shown. The special feature of this cut is the double opening leading from the antrum.

The left picture is made from a section cut immediately within the nasal cavity of the same subject. It shows a section of the bulla ethmoidalis, which is very large, extending downward and forward, partially closing the infundibulum and the hiatus semilunaris.

Figure 25.

Figure 23 is from the same specimen; figure 23 *a* being the same as that at the right in the last, figure 23 *b* being the other half of the section. They show a bulla ethmoidalis cut through. There is also

Figure 26.

a condition sometimes met with, particularly when the hard palate is unusually flat, the floor of the nose, instead of being horizontal, is depressed about the middle, giving a concavity to the floor of the nose.

Figure 24 shows a transverse section through the

frontal sinuses; from one of which there has been no foramen of exit.

Figure 25. Same subject; the section made one

Figure 27.

Figure 28 a.

Figure 28 b.

inch below the former, shows the downward excavation which has occurred in the occluded sinus. In the lower picture the surface of the specimen is shown, the excavation extending into the nasal bone. A

marked irregularity of the ethmoidal cells of the two sides will also be observed.

Figure 26 is also a specimen of unilateral occlusion. This section exhibits the floor of the brain case. It appears as though the secretion of the occluded sinus had formed a retention cyst, the pressure of which has caused perforation of the brain case, the crista galli being bent down almost flat by the growth of the cyst. Unfortunately, I have no antemortem, or clear postmortem notes of the cases. I should expect, however, that the patient presented cerebral symptoms.

Figure 27. Same specimen; shows the effect of the encroachment of the cyst upon the inner orbital wall, which is badly broken down.

Figure 28 shows a horizontal section through the ethmoidal cell, nasal fossæ, etc., at a point indicated in the last figure (No. 27).

These slides are presented with a double object; first, to show what limited reliance is to be placed upon ordinary text-book anatomy of these parts; second, to demonstrate that what are called abnormalities of structure in these parts are far from uncommon.

DO VIVISECTORS INFLICT UNNECESSARY SUFFERING IN THEIR INVESTIGATIONS?

BY E. STUVER, M.S., M.D., PH.D.

Member American Medical Association; Colorado State Medical Society; International Medical Congress Berlin, etc.
RAWLINS, WYOMING.

About July 18, 1897, there was published in the *Rocky Mountain News*, an article by E. K. Whitehead, secretary of the Colorado Humane Society, followed on August 30 by another. In these articles the scientific experimenters of the world are directly charged with brutal, inhuman, wanton and cruel conduct toward animals, in carrying out their experiments and investigations. Physicians are charged with being participators or accomplices in these so-called atrocities, and it is claimed that no real advance in medical knowledge, which could not have been made without it, has followed as a result of vivisection.

The charge that physicians, without sufficient cause, sanction wanton or cruel treatment, or animal mutilations and sufferings which are unnecessary, is a gratuitous insult to a profession animated by the most self-sacrificing and humane instincts of any class of people in the world, a profession which has done more to alleviate human suffering, stay the devastations of plague, diseases and death, to discover and demonstrate the laws of health and causes of diseases, and raise mankind to a higher and better plane, in short to advance civilization, than all other influences combined.

When these facts are appreciated I believe all fair minded people will concede that the medical profession is animated by noble and disinterested motives; that its vivisections and all other investigations and experiments are made in the interests of science, truth and humanity, and not, as has been charged, for the mere sake of performing experiments.

The object of all these scientific investigations is to find out the causes of things, and it was only when inductive science came and put intelligently planned experiments in the place of haphazard experience that a single advance was made. (A. M. S. B. April 10, 1897, p. 318.) On the principles and truths thus

discovered by experimental investigations, the splendid results of our modern scientific knowledge and inventions, our progress in medicine, surgery and sanitary science almost entirely depends.

We who live under the benign influences of modern sanitary surroundings, and in the clear light of the laws of health already demonstrated by vivisection experiments, can not realize the benefits we enjoy until we draw aside the dark pall of time that covers the results of thousands of years of empirical experience. Do this and we behold plague and pestilence sweeping over the land, leaving desolation and death in their track. Here we see cities converted into charnel houses, the streets covered with dead bodies, and not enough well to care for the sick and dying; there we behold uncoffined corpses rolled into great trenches, or left as food for ravening animals, or to pollute the atmosphere. We, who enjoy the immunity afforded by vaccination, can scarcely believe that such ravages were caused by smallpox in London as are so graphically described by the historian Macaulay, who informs us that it was a rare thing at one time to find a person in that great city not disfigured or marked by the dread disease. Experimental investigation has stamped out smallpox, except in communities ruled by antivaccination cranks, and diphtheria appears to be in a fair way to share a similar fate. Still, we are challenged by the hypercritical, hypersensitive and I might say, hysterical advocates of a measure which is designed to be the entering wedge of a system of espionage, surveillance and obstruction to experiments made on living animals: a system that would place the lives of a few dogs, cats, guinea pigs, or other lower animals above science, truth and the lives of thousands of human beings, for however much some of the advocates of the pending measure may try to conceal their real intentions, yet their avowed purpose, as boldly announced by others, is the entire suppression of all vivisection. We are challenged by these misguided people to give specific instances of the benefits arising from vivisection experiments. While anything I may say, probably will not influence radical antivivisectionists, because, as some one has said, "some human beings would deny the multiplication table and the axioms of geometry, if they came in the way of their sentiments," still I hope that fathers and mothers who desire to see their children grow up into strong, healthy and happy men and women, will impartially consider the facts of history and lend their assistance in securing the desired results.

By the vivisections of Malpighi, Waller and Cohnheim we learned how blood nourishes the tissues; by the animal experiments of Aselli and Pecquet, how the chyle is carried into the blood. The processes of intestinal digestion were revealed by the vivisections of Hunter, Magendie and others. Sir Charles Bell and Magendie in the same way discovered the difference between the motor and sensory functions of the spinal nerves, and the experiments of Ferrier and a host of others have so illumined the physiology of the brain and localized its functions that many things which were dark and mysterious a few years ago are now as clear as the noon-day sun. The results of the experiments of Pasteur caused Lister to investigate the influence of antiseptics in the treatment of wounds. This has led to our modern antiseptic treatment which has saved thousands of lives and untold suffering, besides bringing surgery to a degree of per-

fection undreamed of a few years ago. But it may be asked, is this all that vivisection has done? For thousands of years under the regime of empiricism men continued to breathe and re-breathe foul and poisoned air. By living in close badly ventilated buildings they intensified mild diseases into pestilences, and then explained the result as a scourge of the Almighty for a lack of fealty to their faiths. Their homes, their churches and their public halls defied every law of sanitation, so that the death rate of London was 80 to the 1000. In 1674 John Mayow, a young Oxford physician, became sceptical of the prevailing doctrines, and defying society's prohibition of experimentation on animals proceeded to find out how animals breathed. By the painful slow suffocating to death of a few animals in air-tight jars, Mayow demonstrated that the agony and death of a suffocated animal were due to the consumption of a constituent of the air.

As soon as these facts were known the old superstitious notions of disease being caused by ghosts and demons vanished in air, and the results of the sacrifice of a few mice, the wanton, brutal torture it might be called by some, came with healing wings to banish slow poisoning, torture and death from millions of homes, to carry sunshine into gloomy hearts and to give hope and inspiration to heavy laden spirits, to brighten and gladden the present and span the sky of the future with a refulgent bow of promise. Later on, Black, by the aid of more experiments on animals, discovered the effects of carbonic acid gas. Priestley in the same way demonstrated the life-giving quality of his oxygen, and Rutherford and Lavoisier followed the same course in proving that nitrogen would not support life. Thus we see that the foundation stones of modern chemistry were laid by this kind of vivisections.

One of the most signal and conclusive examples of the great value of animal experimentation is the splendid success of the antitoxin treatment of diphtheria, especially in that deadly form affecting the larynx. Where formerly fathers and mothers stood by the death beds of their dearly beloved children, who were slowly strangling, and in agonizing sorrow saw them snatched away by the fell destroyer; where the sympathizing physician, impotent to cope with his relentless enemy, stood by with downcast face, we now behold smiles of joy light up the faces of the parents as they see the roses stealing back to the cheeks of their stricken ones, and the proud happy look of the physician who boldly faces and defeats his old enemy! I ask these fathers and mothers if one such victory as this is not worth more than all the horses that have been sacrificed in attaining the results. And when we consider the thousands of innocents saved to advance and adorn civilization through cycles of the future, we can appreciate the almost infinitely beneficial results that flow from animal experimentation.

We thus see that nearly all our knowledge of physiology, much of that in chemistry, and many of the greatest advances in curing or stamping out diseases have resulted directly from vivisections. We have seen the death rate of London reduced from 80 to 18 per 1000, and in the face of all this the people of this great country are asked to restrict vivisection, to place all operators under inspectors who are to work without pay! It ought to be plain that only two kinds of persons would fill the position under such conditions, the enthusiastic vivisector, eager to dis-

cover the truths of nature, or the bigoted fanatic who would use all the powers of his position to obstruct or prevent the work.

Then, too, the provision to limit this kind of work to those 25 years of age or over would have a most disastrous influence on scientific progress, because in order to train an experimenter in methods of accuracy and precision, and to cultivate habits of careful and systematic observation the work must be begun long before that time of life. Men endowed with a genius for scientific investigation are very rare indeed, and those so gifted should be given the fullest opportunities to develop their faculties during youth when the perceptive powers are keenest, and impressions made on the mind are retained with greater clearness and tenacity than at any other time. Think of the loss science and humanity would have sustained if Carpenter, Agassiz, David Starr Jordan and hosts of other investigators had not been permitted to begin their work before 25 years of age! The whole gist of the matter, however, centers around the question: Are the vivisectors of this country at the present time guilty of inflicting wanton, cruel, brutal and unnecessary suffering upon animals? I say the present time advisedly, because (*American Medico-Surgical Bulletin*, April 10, 1897, p. 321), the evidence presented before the Congressional Committees, and the tales told in pamphlets and papers to influence public opinion are hoary with age. The same pictures and stories which did service in 1874, with scarcely any change have been regvanized, republished and trotted out in their age and decrepitude to mold public opinion in 1897. If the vivisectors of the District of Columbia are the incarnate fiends they have been represented to be, why is it that after a most careful search of over a year their enemies have not been able to justify their attitude by a single case? Even if mistakes were committed twenty-five or fifty years ago (and it can be shown that many of the stories about that day were pure misrepresentations or gross exaggerations) does it follow that scientific progress ought to be hindered, or scientific men of the present time made to bear the odium of by-gone days? If such a rule were followed the noblest and most sacred causes in the world would be obliterated by a crushing load of obloquy.

Draper ("Conflict Between Science and Religion," page 207) tells us "that in order to extirpate religious dissent by terrorism and surround heresy with the most horrible associations," the Inquisition, "between 1481 and 1805 had punished 340,000 persons and of these nearly 32,000 had been burnt." Nor is it necessary that we leave our own "land of the free and home of the brave," for similar examples.

Our own New England witchcraft tortures and executions ought to make us very modest on that question. Of course the victims offered up in the name of religion were only human beings. If they had been dogs, cats, guinea pigs, etc., sacrificed to stay the ravages of pestilence, disease and death, and carry health, happiness and sunshine into every home in the civilized world it would be a very different matter, and it would be eminently proper to call the investigators "unnamable devils."

The crusade of the antivivisectionists from beginning to end has been a series of equivocations, misrepresentations, and half truths. They never have dared to tell the whole truth, and discuss the question on its merits, and some of the strongest evidence that they

have presented is based on statements made by writers who were misinformed when these statements were written, but who later on had the manhood to acknowledge that they had been deceived by antivivisection literature and retract their mistakes. Have these zealous humanitarians had the manhood to publish the retractions along with the original? Have these earnest advocates of justice and right had enough true nobility of character to admit that they had suppressed the truth and perpetrated an injustice against their fellow men? We leave the history of the movement and the justice of the people of this nation to answer these questions.

Even if the human race had never received a particle of benefit from vivisections, according to eminent authorities the animals themselves by the stamping out and relieving of their own diseases have been spared more suffering during the last twenty years than has been caused by all the experiments ever performed in the world, to say nothing of their immunity from disease in the future.

Then too, many of the pathetic appeals and blood curdling recitals of horrible sufferings are based on gross ignorance of physiologic knowledge. If these writers knew that the motor region of the brain was insensitive and that operations on those parts of the brain substance do not cause any pain whatever and that nearly all animals operated on are first rendered insensible to pain by anesthetics they would be spared many useless tears. More real knowledge and less sentiment would be an inestimable gain both to themselves and to humanity. But to show that we bear them no ill-will, indeed that we admire their zeal and enthusiasm, misdirected though it be, we would suggest that they turn their wonderful energies and great abilities into more appropriate channels. If they will put a stop to the wanton, useless and utterly repugnant slaughter of the thousands of feathered songsters, the victims of fashion that are every year killed to ornament the bonnets of women throughout the civilized world, they will prevent more suffering than is inflicted by all the scientific experimenters in existence. If they will prevent the wounding and mutilating of the thousands of animals that yearly drag out a miserable existence and probably starve to death; the chasing of defenseless creatures with horses and hounds until they actually drop dead, and other similar cruel things done in the name of sport; if they will rescue some of the thousands of women and children who are constantly dying by slow starvation in our large cities, they will find their time fully occupied and do a great deal of good. While they are doing this work they can rest assured that the welfare of humanity as well as the interests of animals will be protected and advanced by physicians and scientists as they always have been in the past.

SOCIETY PROCEEDINGS.

Chicago Academy of Medicine.

Regular Meeting, Feb. 11, 1898.

Dr. JOSEPH B. BACON in the chair.

C. S. N. HALLBERG, Ph. G., read a paper on

THE PHARMACOPEIA OF 1900 IN ITS RELATIONS TO THE VARIOUS DEPARTMENTS OF MEDICINE.

In introducing this subject it may be well to give a comprehensive definition of the pharmacopeia, what it is, its purpose and its functions. Medical dictionaries and other standard

works give definitions which for practical purposes are wholly unsatisfactory. As a rule these works define a pharmacopeia "as an authorized work containing a collection of formulae," etc. The publication of a pharmacopeia was the necessary and logical outgrowth of the confusion in the identity and strength of medicine existing up to nearly the beginning of the present century. Nearly every medical man of any considerable note and ambition became the author of a dispensatory, each one differing, often as to essential particulars anent potent and important remedies. These works were adopted for certain medical centers such as, Nuremberg, Venice, Augsburg, Cologne, Edinburgh, etc., and were later followed by local pharmacopeias such as those, for instance, for London, Dublin, Paris, Berlin, Hanover, etc. The first half of the present century saw these local pharmacopeias superseded by works of national authority until now, at the close of the nineteenth century, no country can maintain position as a nation without a pharmacopeia; one of the latest, but by no means the least creditable, being that of Japan. The most important republics of Central and South America have their own pharmacopeias. In some, foreign pharmacopeias are employed, chiefly the French Codex and German Pharmacopeia. The republic of Costa Rica adopted officially, in 1897, through La Facultad de Medicina y Cirurgia at San Jose, the United States Pharmacopeia as the standard authority. In Canada and the British provinces the United States Pharmacopeia is used more than the British pharmacopeia. The project of an imperial pharmacopeia for the British Empire is meeting with but little favor and its realization is doubtful. Attempts have been made toward the formulation of an international pharmacopeia and also a Pan-American one. The former will be considered by the International Pharmaceutical Congress which is to meet in Paris in 1900.¹ The first United States pharmacopeia was issued in 1820 and each decade subsequently has seen a revision. The one now official, designated as the seventh decennial revision, was adopted Jan. 1, 1894. The earlier editions and revisions were the work chiefly of such medical scientists as Samuel L. Mitchell of New York, Erastus Torrey of Vermont, William Tully of Connecticut, Nathan Smith of Connecticut, Valentine Mott of New York, Samuel P. Griffith, Joseph Parrish, George B. Wood, and Franklin Bache of Philadelphia. The Committee was increased to twenty-five members in 1880, comprising botanists, chemists, pharmacists and physicians in nearly equal numbers. To these were added one representative from each of the medical departments of the Federal Government: the Army, the Navy, and the Marine Hospital Service. The National Committee on Revision is elected by a convention constituted by delegates from incorporated medical and pharmaceutical societies and colleges, which meet in the city of Washington, D. C., decennially. This convention also adopts rules and principles for the instruction and guidance of the Committee on Revision. The next convention will assemble in Washington in May 1900. From this brief résumé of the history of pharmacopeias it will be observed that a pharmacopeia is essential to every civilized country, and the work of revision is one of great interest and importance. Although the United States Pharmacopeia has never been legalized through National enactments, it is recognized as the legal standard in all legislative enactments of the various States pertaining to the practice of pharmacy and the prevention of adulterations in drugs and medicines. It is therefore *de facto* the legal standard for the entire United States as much as though its authority had been declared by congressional *fiat*. No especial attempt has so far been made to legalize the pharmacopeia, through the Congress of the United States, but since the National Government is represented in its creation and accepts its standards quite as readily as do the State and local governments, there may be no need for the Federal insignia, at least not until a National department of health is created.

The "United States Pharmacopeia" may be defined as an authoritative compilation or work creating: 1, standards for the identification, purity, strength and quality, and 2, giving directions, for the purification, valuation, preparation, compounding and preservation of drugs, chemicals and medicinal substances.

The French pharmacopeia is also called the "Codex Medicamentarius." This last title expresses the scope and functions of a pharmacopeia better than any other. It should be the pharmacological code for physicians and pharmacists alike. With a pharmacopeia as up to date as its periodic revision admits, with thoroughly educated and experienced pharmacists, the physician is assured not only of uniformity in product, strength, purity and quality but also that such medicines will be prepared according to the best and most advanced methods of the pharmaceutical arts.

While the "United States Pharmacopeia," from a scientific

¹ Journal of the American Medical Association, Vol. xxvii.

standpoint is undeniably in advance of all other pharmacopeias, yet it lacks certain features to render it more serviceable, and consequently more generally acceptable to the medical practitioners. The first of these deficiencies is in the pharmaceutical preparations, particularly in such classes as are of solid form and also such as are intended for external use. Another deficiency is that the revised edition does not with sufficient accuracy contain as many new substances as have fairly proved their efficacy, promise and utility as therapeutic agents, as it should. Thirdly it lacks certain general information which should be incorporated as an authoritative guide to the more intelligent use and application of various remedies. In this last category should be included the maximum dose of all toxic and potent substances and their preparations. While pharmacology (or the science devoted to the action of drugs) and therapeutics (or the science devoted to the indications for and selection of remedies), are not within the scope or functions of a pharmacopeia, still the certain safe and accurate method of exhibition and administration of remedies can not be realized unless their respective forms be based upon these fundamental considerations. It is not otherwise possible to realize the motto of Asclepiades, *cito, tuto, jucunde*.

Whatever improvement be necessary in the new pharmacopeia, in the direction of its greater therapeutic utility, must come from medical men. There may be superfluity of remedial substances in a pharmacopeia while no authoritative forms for their administration are given. On the other hand, the preparations though made after elaborate processes may be so defective as to impair their therapeutic usefulness. This is particularly true of solid preparations, especially those intended for external use, while nearly one-half of the 1000 articles of the "United States Pharmacopeia" are preparations, these comprise but thirty-three classes, and of these only eleven are solids, six for internal and five for external use.

The French pharmacopeia has sixty-four classes in which there are thirty-four solids, eighteen for internal and sixteen for external use. The British pharmacopeia has thirty-five classes including thirteen solids, four for internal and nine for external use. It is particularly strong in ointments, having forty-four, and is the only pharmacopeia in which an attempt has been made to discriminate as to the selection of the vehicle employed for ointments of varying use. The German pharmacopeia has forty-five classes with twenty-two general formulæ giving directions for compounding any number of as many different classes of preparations. There are twenty-three classes of solids about equally divided into preparations for external and internal use.

While a compilation of about five hundred formulæ for preparations of a polypharmaceutical or ephemeral character was published by the American Pharmaceutical Association in 1887 and revised in 1895 under the title "The National Formulary," this work does not carry authority as a standard like the pharmacopeia. The "National Formulary" has been exceedingly useful in introducing greater uniformity into such preparations as elixirs, syrups, pills, etc., but its utility is hampered through the difficulty of acquainting physicians with a semi-official work. Familiarity with and adherence to accepted standards are more likely to be secured through one comprehensive work of official character than through several.

From these observations the following suggestions are offered for the work of the revision in these respective special departments of medicine:

DISEASES OF THE EYE.

Identification and determination of comparative value of the mydriatic alkaloids, with especial reference to those of the solanaceous plants and their derivatives.

Formulas for collyria, especially solvents.

Investigation of the employment of the lamellæ (gelatin-disks) containing alkaloids for solution in the eye, instead of water solutions.

List of ointments used and character of vehicle employed, with reference to the preference of the paraffins to the more absorbable animal and vegetable fats.

DISEASES OF THE EAR, NOSE AND THROAT.

Report on antiseptics, anesthetics, anodyns, absorbents, astringents, demulcents, emollients and protectives used in substance or in the following forms, with especial reference to solvent or vehicle used: Gargles, insufflations, injections, lotions, oleates, pastilles, tablets, troches, vapors, cereoli (antrophore), pastes, electuary, confection, sprays, oils (medicated), stylus, suppositories, cigarettes, papers (fumigating) (inhalant), ointments, cerates, plasters.

SKIN AND GENITO-URINARY DISEASES.

Report on antiseptics, astringents, absorbents, anesthetics, anodyn, caustic, hemostatics, parasitides, protectives, rubi-

facients, styptics and vesicants used in substance or in the following forms, with especial reference to solvent or vehicle; also comparative study of vehicles as to ratio of absorption and classification of ointments, cerates, suppositories, plasters and unctuous preparations for external use: Baths, cataplasms, caustics, crayons, sponges (prepared), fomentations, oils (medicated), enemas, lotions, powders, soaps, solution, injections, suppositories, cotton, gauze, pomades, ointments, cereoli (antrophore), stylus, cerates, plasters, plaster mulls.

DISCUSSION.

Dr. WM. L. BAUM—I have always thought that the interest taken by the medical profession in formulating a new pharmacopeia was entirely inadequate to the needs of the time, and I can say truly that in our specialty of dermatology and genito-urinary diseases, a great improvement could be made, especially in the matter of ointments. The ointments that are prescribed today are of various kinds, as Professor Hallberg has pointed out, those in which it is intended that the base should be absorbed, and others where the ointment is simply used as a protection to the external integument. *i. e.*, those whose therapeutic value does not depend upon the direct resorption of the medicament. There should be a division of ointments into classes. They should be classified as to whether they are intended as absorptive agents or as local protective applications. This should not be a very difficult task, in the light of the work that has been accomplished, especially in this specialty. We have at our command a large quantity of material which has been collected by laborious research work in the laboratory and in hospitals by eminent men throughout the world, giving the quantities of the base resorbed of ointments made up with different vehicles. There are many changes that could be very profitably brought about in the matter of emplastrums; here we also wish to have an absorptive element as the main feature of the plaster. The plaster, owing to the manner of its preparation, fails to carry out the therapeutic intention; that is, we have compact plasters where we should have plasters which will allow the free circulation of air, so that instead of having a plaster in which the active therapeutic agent is resorbed, we frequently find laceration of the skin. In the matter of the various preparations which are used in genito-urinary work, the pharmacist loses sight of the fact that the physician wishes to have a distinct therapeutic action exerted upon the genito-urinary apparatus. The genito-urinary tract is not an absorptive mucous membrane, or best to a very slight extent, so that preparations employed in this direction should contain but little of the oil and lard preparations, but should be such as will enter into active combination with the normal secretions of these membranes. While we do not get a good therapeutic action from the various ointments that are injected into the genito-urinary tract, a smaller quantity would give the same therapeutic effect if made up of demulcents, or some vehicle which enters into active combination. I have long ago discarded the formulæ of the "U. S. Pharmacopeia." I prefer to write out directions for the druggist as to the preparation of all ointments and remedial agents applied to the genito-urinary tract proper. It is but fitting that the medical profession should take an active interest in the formulation of the various methods of pharmaceutical preparation upon which much of the success of therapeutic measures depends.

Dr. C. D. WESCOTT—We have reason to think that it makes much more difference how a thing is prepared that goes into the eye than in regard to preparations that are used upon the skin, or that go into the stomach or rectum. It is here that small things are more important than in some other places. In regard to the preparation of collyria, it should be almost criminal for a druggist, in these days, not to prepare such a solution in a clear and sterilized condition. To illustrate the importance of having the solution for application to the eye sterile and free from visible particles, patients have frequently come to me with the story that the eye drops which I had prescribed were irritating to the eye, and brought me the bottle to have me tell them if that was the proper thing and what I had ordered. Such solutions, prepared by druggists about town, have frequently contained sediment or particles of dirt. It is not simply a light flocculent sediment, such as may be precipitated from lake water on standing, but visible particles of dirt. Any one of these particles would be regarded as a foreign body resting on the cornea, and would be irritating if under the lid. After I have boiled and filtered these same solutions, they have been used without any irritation or trouble. There should be a rule by which druggists should prepare collyria with boiling water, and they should be filtered while hot and given to the patient in a sterilized condition. Then it rests with the oculist to give such instructions that they shall remain sterile.

In regard to the discs, I quite agree with Professor Hallberg that they should be recognized in our Pharmacopeia, and my experience teaches me that gelatin is the best excipient for the manufacture of these discs. My experience would also indicate that zinc salts and other similar compounds should not be used in this form. We have quite a number of discs of this sort, prepared by the John Wyeth Company. The discs which contain cocain, atropin and eserin, and other active principles of drugs, with gelatin as the excipient, give us remarkable satisfaction. As Professor Hallberg has said, they keep the drug in a permanent condition; there is no danger of decomposition or of alteration whatever, and the application of drugs to the eye in that form is advantageous. But some of the discs with which we have been furnished have something else as the vehicle; perhaps it is boric acid, and those discs have been irritating. A gelatin disc, containing a minute dose of eserin, is not very irritating; but put up in the other way with boric acid it is. I once applied a disc containing a minute quantity of sulphate of zinc, and the experience was very painful to the patient and disgusting to me. Such a thing is not to be tolerated. So the revisers of the Pharmacopeia should have specific advice in regard to these points.

With reference to the ointments to go into the eye, we have all had sad experiences in this direction. One of the commonest ointments which we employ is that made from the yellow oxid of mercury. It is possible to obtain an impalpable powder of the yellow oxid, and when mixed with pure vaselin or lanolin in a proper way, it is absolutely smooth and unirritating to the conjunctiva; but unless we send our patients to a druggist in whom we have absolute confidence, and who has been repeatedly cautioned in regard to these ointments, we get mixtures that are positively harmful. We get mixtures in which we can see, with the unaided eye, palpable particles of the yellow oxid, which, lodging upon the surface of the cornea, act as cauterizing masses, and patients have come back, especially those who do not heed the directions of the oculist in regard to going to certain druggists for the ointment, with fearful irritability of the eyes and with the ointment to show.

In regard to excipients again, I have had various experiences which indicate that some of the things which come under the head of vaselin and petrolatum are not pure, and I have been told that some of the white vaselins are bleached with sulphuric acid. I may not have been properly informed in regard to this point; but at all events they are prepared in an improper way and are very irritating to the eye. There should be some absolute rule with regard to the preparation of vehicles for ointments that go into the eye, so that if a petrolatum preparation is used it will be absolutely pure and non-irritating. In order to avoid the irritating properties of vaselins I began, when lanolin was introduced, to use it as the vehicle for eye ointments. At first lanolin seemed to act very well, and then I found that it became rancid like other animal fats, and I once applied some old yellow oxid ointment with lanolin as the vehicle to my own eye, and was much surprised to get considerable burning; so I have discarded lanolin. Recently I was informed that lanolin is sometimes irritating because it is not made in a proper way and contains a free acid. It seems to me that much will be done to aid specialists in diseases of the eye, if we may have standard directions in our new edition of the Pharmacopeia in regard to the preparations that I have mentioned.

Dr. GEORGE F. BUTLER—There is room for improvement in the Pharmacopeia, although in some respects the present edition is superior to the older editions. In spite of the faults, however, physicians would succeed better if they adhered more closely to the pharmacal preparations. Sometimes our failures are due to unreliable preparations, through the fault of the druggist, but I believe the average druggist is as honest as the average physician.

Many physicians know nothing about pharmacy. While they have learned by experience that in certain conditions various preparations are more active than others of the same drug, they are ignorant of the reason for this difference. It takes skilled pharmacists to instruct them in this particular. The suggestion, therefore, that a radical change be made in the next Pharmacopeia, and that it be the result of the combined effort of skilled clinicians and pharmacists, is an excellent one. Many drugs and preparations should be added to the next edition, and possibly some that are already official should be omitted. Within the past ten years a number of very important medicinal agents have been brought to the attention of the profession which are deserving of a place in the Pharmacopeia.

A few thoughts occurred to me while Dr. Wescott was speaking, as to some of the reasons for our frequent failures in therapeutics, not so much the fault of the Pharmacopeia as that of the druggist. Dr. Wescott spoke of infected solutions

aggravating eye troubles. We have similar difficulties with internal remedies. Those of us who practice general medicine know, for instance, how valuable an agent chalk mixture is in certain cases of diarrhea. Perhaps some of the gentlemen present have given this remedy where it was unquestionably indicated, and found the symptoms markedly intensified after its administration. The difficulty was not in the selection of the wrong remedy, but of an impure, infected preparation. Cinnamon water, from which the chalk mixture is prepared, becomes upon long exposure contaminated with microscopic plants, which aggravate the intestinal trouble.

The Pharmacopeia directs how preparations should be concocted, and kept; yet how frequently these directions are disregarded.

As I remarked before, the fault is not with the Pharmacopeia in such cases, but with the carelessness or dishonesty of the druggist.

Considering the physician's ignorance of *materia medica* and the physiologic action of drugs, and the adoption and administration of various nostrums recommended by the profession as panaceas, together with the unreliable pharmacopeial preparations which too many druggists dispense, it is no wonder there are so many failures in our treatment.

It is high time for the advanced and aggressive physicians and pharmacists to unite, and endeavor in every way to counteract the prevailing tendency toward therapeutic nihilism. One way is to popularize the Pharmacopeia, and educate the physician to prescribe reliable pharmacopeial preparations, depending less upon the irrational therapeutic claims of the secret medicine manufacturer. The Pharmacopeia of the United States should be used as a text-book, not only in schools of pharmacy, but in those of medicine, so that every medical student may become thoroughly familiar with its contents.

The suggestion of Professor Hallberg as to classification is an excellent one. We are using drugs for the relief or cure of disease, and the only rational classification for a pharmacopeia, as well as for a *materia medica*, is a therapeutic one.

Dr. WILLIAM F. WAUGH—It is to be hoped when revision is made and the preparation of ointments, plasters, etc., is considered, that some experiments will be made as to the efficiency of the various preparations. I am inclined to think that some of the proprietary preparations are better than those of the pharmacopeia. For instance, I have never been able to get a plaster which would compare in efficiency and pleasantness for use with "canthos" plaster made by Johnson & Johnson. Knowing that in this we have a preparation of such undoubted efficacy, I trust the revisers of the Pharmacopeia will take it into consideration. As to gelatin discs, I fear that we have a comparatively limited number of agents which can be used in that way. Dr. Charles L. Mitchell of Philadelphia, who knew more about gelatin than anyone I ever met, was accustomed to say that nothing but experiments would show what would do in any new combination. He mixed gelatin with pepton for me once for rectal suppositories, and the patient wore them in his rectum all night and reproduced them in the morning without the slightest evidence of softening.

Dr. A. LAGORIO—There is one point that I hope will be discussed a little more fully and that is the preparation of pills. We have pills which after a while become so hard that we can not break them. I remember purchasing a bottle of Blaud's pills, which were absolutely insoluble. Something should be done whereby these pills can be kept in good condition, also suitable excipients should be used in all the different kinds of pills, making them soft, pliable and easily dissolved. I agree with Dr. Butler that a good deal depends upon the honesty and dishonesty of pharmacists. I am fully in accord with the sentiment that physicians and pharmacists should come together and see what they can do toward improving the new Pharmacopeia. When it comes to the revision of the pharmacaceutic and therapeutic parts of the Pharmacopeia the experience of every specialist in these branches will be of great value.

Dr. GEORGE F. BUTLER—While Dr. Lagorio was speaking I thought how careful the surgeon is to have his hands and instruments perfectly clean, in order to avoid the possibility of infection. If a surgeon infects a patient his conduct is looked upon almost as criminal carelessness, yet the physician pours medicines down the throat of his patient without regard to quality or purity, and with but little thought of the physiologic action of his drugs. If the physician would exercise one-half the care in the treatment of his patients that the surgeon does in his operations we should have fifty times better success. Just so long as physicians are lax in these matters, just so long will our patients suffer and die from improper treatment and surgeons and the laity will have some justification in their accusation that "there is nothing in drugs." There is a great deal in proper therapeutics. Compare the surgical methods

of fifty years ago with the operations of today. Are the present results due entirely to the skill of the operator? No; but to cleanliness and *drugs*—anesthetics and antiseptics. There is room for similar improvement in internal medicine, and it is now imperative that we should awaken to this fact and do away, as it were, with the red-hot iron and swab of melted pitch, devoting more time and thought to pharmacology, pharmacy and rational therapeutics.

Dr. J. G. KIERNAN—If every prescription bore the proper directions and the preparation be ordered made according to the "U. S. P.," some of the abuses to which Dr. Wescott referred might be guarded against. Furthermore, if prescriptions be not put up in a particular manner, or as specified, it seems to me that penalties could be enforced against the individual for not complying with the directions of the physician. As it is, without some such directions we afford a lee-way for unscrupulous druggists. With regard to the points directly involved in the pharmacopeia, very little can be added to what has already been said. With reference to the question of pills, a number of points might be raised. There is no doubt that in certain nervous conditions sugar-coated pills will be absorbed when gelatin-coated pills will not. In certain cases of hysteria and melancholia we will every now and then find that by giving sugar-coated pills, drugs produce their effects, while the gelatin covered pills pass the rectum unchanged. These are questions that will have to be settled by careful experimentation. The point brought up by one of the Fellows in regard to the pharmacopeia not being one of cosmetic pharmacy but one of therapeutic pharmacy, is well taken. There are a number of points that could be raised along the lines of the various specialties, particularly with reference to the specialty of nervous diseases, but which also involve the genito-urinary specialty and also that specialty from the standpoint of the syphilographer. Many of the questions about ointments are particularly pertinent. Some years ago when the question of lanolin came up, a Fellow of the Academy, now deceased, held the opinion that the vehicle did not make much difference; that the petrolatum of the pharmacopeia and the indefinite and proprietary vaselins and paraffins meant approximately the same thing. Professor Hallberg made a blue ointment with lanolin for inunction purposes, of which he gave me a sample and of which I gave this Fellow of the Academy also a sample. He had a patient with pediculus pubis and gave him lanolin preparation, with which he succeeded in killing the pediculi but salivated the patient considerably. That experiment and a number others would indicate the line that should be followed with reference to ointments. Then there was another question raised by a Fellow of the Academy, who is unable to be present tonight on account of illness, regarding the parasites and parasitocides. He pointed out that the itch insect was more or less given to living to a certain degree on the sebum, consequently a preparation made of lanolin would not be as toxic to the acarus as one made of lard or some other preparation, and that therefore some of the ointments, like the sulphur ointments, which were intended to reach the itch, might be better made from lard and preparations of that kind. This is only one of a dozen suggestions that might be made along the same line. I think, however, the old conception of the authors of the pharmacopeia should be carried out. We forget how high these men stood, not only in medical science but in general science. I am referring now particularly to those who were prominent in originating the Pharmacopeia of the United States. The two first dispensaries contain therapeutic hints which, if followed long ago, would have saved a great many lives. One of them, for example, Thatcher's "Dispensatory," contains an excellent description of Brand's method of treating typhoid fever with cold water, a form of treatment charged to the credit of the other side of the water. Professor Hallberg quoted Samuel L. Mitchell. If there ever was an unrecognized scholar in medicine it was he. If we go back and read the old "New York Medical Repository" and Mitchell's introduction to Erasmus Darwin's "Zoonomia," which went through nine American editions, we would see how high the earlier American physicians stood, especially those who were prominent in the production of "Tilton's Pharmacopeia" and also of the "Pharmacopeia of the Massachusetts Medical Society." The latter contains bryonia, aconite and other things whose use the eclectics and homeopaths claim to have originated, but really took from works of this character. Mitchell was a biologist. He was a student of physiology, geology and of evolution. His preface to Charles Darwin's grandfather's "Zoonomia" showed that he and his medical contemporaries belonged to a cultured set. These people appreciated the necessity to the physician of the pharmacopeia, and from their labors grew up this decimal pharmacopeia. But latterly, when Philistinism came into

vogue in America, this whole question of the pharmacopeia fell into the hands of the pharmacists alone, who, of necessity, had to deal with it purely from the standpoint of pharmacy. It seems to me, Americans should, in taking a forward step, go back to the old period when they took so much interest in general science. This would be a good beginning along that line. With all our modern pathologic and bacteriologic work we have gone back to the old workers on biology, and it is a good thing to follow their example along a therapeutic standpoint as well.

PROFESSOR HALLBERG (closing the discussion)—The general sentiment seems to be directly in line with the suggestions offered, and I can only emphasize from my limited sphere of observation as a pharmacist many of the charges that have been made with reference to careless and faulty preparations. Right here is where the general formulæ for a great many different preparations would be of great service. If the Pharmacopeia had a general formula for the preparation of collyria, for example, it does not need to enumerate a great number of different collyria. It may give one or two examples, but also must dictate the official process and method by which the collyria shall be prepared. This certainly would be very valuable. Dr. Butler's reference to chalk mixture and cinnamon water is susceptible of different interpretations. Chalk mixture very quickly spoils in summer. If a prescription is to be repeated and the bottle containing the mixture be brought back to be refilled the chances are that the mixture will quickly ferment when put in the second time. A bottle should never be used a second time for chalk mixture, because chalk mixture is exhibited during the heated season. Preferably a new bottle should be used. The point made about cinnamon water and the careful surgeon keeping everything aseptic is a good one that has to be impressed upon the younger pharmacists with great emphasis. The rising generation of pharmacists does not seem to have the least conception of what is proper. In my position as teacher and conductor of laboratory classes at the Illinois University College of Pharmacy I have the greatest difficulty in warning students against vulgar behavior, such as picking teeth or sticking fingers in ears while at work, perhaps while making pills, folding powders, and against general uncleanness of that character. As I do not know what Dr. Waugh has been in the habit of using as cantharidal plaster I will prepare a plaster of the official cantharides cerate that will bring about the desired result much quicker than any proprietary preparation. If there be any perfect preparation in the Pharmacopeia it is the cantharides cerate, when properly made and thickly spread. Gelatin is a vehicle which is not adapted to a great many substances, although Dr. Mitchell has made a success of it. He is one of the largest operators now of gelatin plates for photography in this country, and so he has worked gelatin to its full extent. As to the question of pills, I purposely picked out ointments as a starting point. I should be glad to have the Academy appoint a committee to take up the work that has been suggested, because the Fellows are specialists in these branches. Some one should be appointed to take charge of the mixtures for internal use, represented by the pills and their modifications, powders, capsules, etc. I would be glad to make up a similar compilation on pills and other preparations for like use, on some such plan as that for ointments. Some compound cathartic pills made twelve years ago are as hard as rocks, but they are of resinous extracts, such as colocynth and jalap, calomel and gamboge. This pill will pass through the stomach intact without any doubt, but when it gets into the intestines and the alkaline secretions, there come in contact with the pill, they act as a solvent upon the soap in the mass; the soap swells, the pill becomes disintegrated, these resinous constituents slowly and gradually dissolve and produce their desired effect, and in this manner the irritation is gradual and not sudden. I am satisfied pills of that kind are far more desirable and produce evacuation much less painfully than the pills advertised by means of an illustration, which I have characterized as "boiler-shop pharmacy," the pills being represented so hard that they can be driven through a plank with a hammer. That is a therapeutic as well as a physical monstrosity. Last year I had occasion to investigate this subject. I tried various forms of pills, the hard compound cathartic pills, a great many other kinds, and also the "friable pills." I found by treating them with a digestive fluid, which consisted of a little ox gall, sodium chlorid and bicarbonate, that the exceedingly hard, rock-like pills disintegrated and dissolved quickly and completely, while the friable masses did not disintegrate so rapidly, and even after three hours, at body temperature, they were still undissolved, leaving a residue of from 25 to 50 per cent.

I was much pleased to hear the frankness and emphasis with which Dr. Dickerman endorsed the project of the new Pharma-

copeia, saying that the Pharmacopeia should be more adapted for reference by the physician. The great trouble with both medical and pharmaceutical practice in this country at the present time, and for several years past, is that the average medical student does not obtain information concerning official remedies. His information is obtained chiefly from text books or from teachers who often have an inadequate conception of pharmacy, even though teachers of materia medica. I remember some twenty years ago seeing a professor of materia medica place on the table, when lecturing on tonics, "Plantation Bitters" and "Hostetter's Bitters," using these as typical preparations of bitters and tonics. It is not much better today. Physicians seem to know more about the multitudinous proprietary articles than they do about the official preparations.

There should be no objection to some kind of supplementary therapeutic classification in the Pharmacopeia to which reference could be made. I do not think the Pharmacopeia of the United States should be placed in the hands of the pharmacists alone for revision. At the last convention a number of medical men were placed on the committee, but only one from Chicago attended the meeting. I do not advocate directions in the Pharmacopeia as to therapeutic indications of any drug or preparations. The point I want to emphasize is that the work of revision should consider the therapeutic usage of these respective preparations, heretofore formulated almost entirely from a pharmaceutical point of view. If a certain agent were to be used, it was only a question as to what vehicle would make the best or smoothest mixture, or in the case of an ointment present a nice, elegant appearance, one that would be stable and otherwise be superficially satisfactory. Physicians have not taken the active part in the work of the Pharmacopeia in recent years that they did in the beginning. Pharmacists have been left almost entirely to their own resources in formulating these preparations. They are not necessarily familiar with the conditions that are involved. It is for that reason medical men, and especially specialists, should take up the various preparations and make such changes and modifications in the vehicles as are suggested from a therapeutic standpoint.

I hope the coming revision of 1900 will be as far in advance of the present one as the present one was in advance of the one issued in 1880.

A committee, consisting of Drs. Baum, Butler, Brower, Cuthbertson, Dickerman, Fütterer, Hallberg, Kiernan, Lagorio, Moyer, Pinckard and Wescott was appointed to assist in revising the next Pharmacopeia, with full power to act.

Chicago Medical Society.

Weekly Meeting, March 16, 1898.

Dr. ARTHUR D. BEVAN reported a case in which he showed the value of specific treatment in syphilitic fracture cases. The boy was 14 years of age. The case was presented as a bit of evidence showing distinctly the value of antisyphilitic treatment in cases of fracture in syphilitic individuals. He was glad of the opportunity of showing such a case because several times, in a medico-legal way, the question had been presented to him as to whether he had any definite evidence that syphilis delayed union or prevented it in cases of fracture. The present case was submitted as evidence that syphilis does delay union and prevent it, because the two operations were identical. After the first operation union failed to take place, but after the second, and the use of antisyphilitic treatment, the bones were found in perfect approximation with good, firm union.

Dr. EFAA A. DAVIS reported three cases of tetany, which presented the characteristics of that disease. One of the patients was exhibited.

Dr. CLARA FERGUSON showed cases of Friedreich's disease and hemiplegia.

Dr. J. HOLINGER showed a case of hydrorrhea nasi in a woman 28 years of age, married, and mother of three children. There is no disease of the upper air passages. During the first month of her first pregnancy, about five years ago, she caught cold in the nose, which gradually grew worse, so that at the present time the discharge from both nostrils is quite profuse. She uses from twelve to eighteen handkerchiefs daily. She is perfectly well otherwise. Secretions from the nose were examined bacteriologically and found to be negative.

Dr. JOHN RIDLON showed an interesting case of anterior poliomyelitis complicated with dislocation of the hip joint.

Dr. D. W. GRAHAM exhibited a case of double congenital luxation of the hip-joints.

Dr. D. N. EISENDRATH exhibited a babe, born February 23,

with encephalocele, which was produced by a midwife in delivering the woman.

Dr. BEVAN showed a specimen of large sarcoma of the kidney, removed about two months ago. He also exhibited a surgical kidney removed from a man 37 years of age, who, at the age of 14, received a crushing injury to the pelvic bones, the urethra and triangular ligament, producing extensive traumatic stricture. The case showed how a purely mechanical cause may produce an extensive lesion, resulting in death of the patient.

PRACTICAL NOTES.

Methyl Spray in the Vomiting of Pregnancy.—Lefour reports a serious case cured with energetic spraying the entire length of the spine with methyl chlorid.—*Sem. Méd.*, February 53.

Powder for Painful Ulcers of the Cervix.—Insufflate on the cervix, through a speculum, the following powder, and tampon: Tannin, 2 grams; lycopodium, 5 grams; euphonia, 10 grams; compound opium powder, 5 grams.—*Lutaud, Journ. de M. de P.*, February 27.

For the Incontinence of Urine and Fecal Matters in General Paralysis. Athanassio recommends the following: Potassio-ferric tartrate, 1 gram; tincture of nux vomica, xv to xx drops; decoction of krameria and decoction of cinchona, aa 100 grams; to be taken by tablespoonfuls during the twenty-four hours.—*Semaine Méd.*, February 23.

Formol in Axillary and Paimar Hyperidrosis.—Unna recommends a salve containing ten to twenty grams of the commercial solution of formol combined with thirty grams of lanolin or vaselin. It diminishes the amount of perspiration and abolishes the odor, but radical cures are extremely rare.—*Sem. Méd.*, February 23.

Hair Tonic.—Dietrich recommends the following wash: Quinin hydrochlorate, 4 grams; tannin, 10 grams; alcohol (60 per cent.) 880 grams; tincture of cantharides, 10 grams; pure glycerin, 60 grams; Cologne water, 40 grams; vanillin, 10 centigrams; pulv. sandal wood, 5 centigrams. For external use. Set aside five days and filter. Apply and rub well into the scalp every other day.—*Prog. Méd.*, February 36.

Combined Thyroid and Thymus Treatment had been found much more effective than the thyroid alone in cases of struma, by Gaibiesi, who also states that it was not followed by any of the occasional secondary effects of the thyroid alone. He administered twice as much of the thymus as of the thyroid preparations, suspending all treatment every few days.—*Klin. therap. Woch.*, March 6.

Prophylaxis of Menorrhagia after Childbirth.—Pinard advises vaginal irrigations with two liters of boiled water at 50 degrees C., as a preventive of the excessive menstruation that frequently accompanies the return of the menses when the mother does not nurse the child. The irrigations are made morning and evening, but in case of established menorrhagia three or four times a day.—*Méd. Mod.*, February.

Severe Icterus After the Use of Lactophenin.—L. Hahn reports that he has been using lactophenin for a year and a half with great satisfaction, especially in ileotyphus and for children, as it reduces the fever and restlessness without affecting the pulse or strength. But he has witnessed the development of two cases of severe icterus in consequence of its use, making sixteen now on record.—*Deutsche Med. Woch.*, March 3.

Tingling Symptom in Scarlet Fever.—A new clinical symptom has been noted in scarlet fever, appearing with the eruption, exceptionally preceding it: a transient sensation of heaviness and tingling in the hands, rarely in the feet. It was noted seventy-nine times in 100 cases in adults, usually ascribed by the patient to an uncomfortable position in bed. It may prove an aid in the diagnosis of deceptive cases, especially in the retrospective diagnosis when the eruption was imperceptible.

It has never been found in other eruptions.—*Presse Méd.*, March 5.

Surgery of the Sacro-iliac Articulation, for Caries. Rieder reports in the *Deu. Med. Woch.* for February 10, a case of extensive tuberculosis of the sacro-iliac symphysis and os innominatum, successfully operated with a large incision entirely encircling the latter, to open up all the spaces into which the pus might have found its way downward. He is inclined to attribute much of the success to the after-treatment with the permanent bath, which rendered bandages, etc., unnecessary and induced rapid and perfect granulation, with no effort nor pain on the part of the patient, who now walks without a cane and with scarcely any defect perceptible in his gait. Rieder notes that in damage cases after trauma the sacro-iliac synchondrosis should be carefully examined before admitting the idea of simulation. The quite pronounced atrophy of the lower extremity on the affected side is frequently a guide in such cases. He advises in operating that a wide opening be made in the pelvic floor near the rectum, to allow the freest possible outlet to the pus.

Local Treatment of Articular Rheumatism.—Painting the articulations with methyl salicylate relieves the pain rapidly. Cover with oiled silk and cotton to prevent evaporation: or the following salve can be used: Liquid vaselin, 20 grams; methyl salicylate, 12 grams. If the wintergreen odor is disagreeable, salicylic acid can be substituted, although less effective: Vaseline, 20 grams; salicylic acid, 4 grams. Or the combination: Vaseline, 25 grams; salicylic acid, 4 grams; sodium salicylate, 3 grams; extract of belladonna, 1 gram. Guaiacol has a pronounced antithermic effect and rapidly soothes the pain. It can be applied pure, but it is best to use one gram at a time in 5 grams of 85 per cent. alcohol: or it can be mixed with vaselin: Vaseline, 25 grams; guaiacol, 4 grams. The following combination is very effective but has a disagreeable odor: Vaseline, 30 grams; methyl salicylate, 5 grams; salicylic acid, 2 grams; guaiacol, 4 grams. All of these substances are readily absorbed by the skin.—*G. Lemoine in the Nord Méd.*, February 1.

Medicines that Should Not be Prescribed in Powders can be classified into: 1, those that absorb moisture readily from the air; 2, those which form a fluid in combination with other substances; and 3, those that are decomposed by the oxygen of the air and change color. In the first class belong the acid phosphates and their derivatives, the phosphoglycerates. These salts put up in powders liquefy in twenty-four hours; also sodium bromid, which is extremely deliquescent; crystallized calcium chlorid; strontium chlorid; ammoniac citrate of iron and ferrico-potassic tartrate; piperazin and lysidin; chloral, dry vegetable extracts and, in general, all products prepared by evaporation in a vacuum, especially, dessicated peptones and extracts of animal organs. The second group includes the substances that alone are not affected by the air, but combined, absorb moisture rapidly; such are antipyrin and sodium salicylate. The third group comprises the alkaline and ferro-alkaline iodids and the aristols. A little trick that sometimes prevents trouble is to add a certain amount of licorice powder or cinchona; also to keep the powders in an air-tight glass jar.—*Journ. de M. de P.*, February 27.

Fasting as a Cure for Acute Infections.—Professor de Dominicis has been forced to the conclusion that the mysterious cause which transforms inoffensive bacteria passing harmlessly through the organism, into virulent pathogenic germs, is the failure of the digestive apparatus to dispose normally of the food. Even the simplest, scantiest diet will produce putrid decomposition if not digested, and the alimentary canal become a toxin factory and a fine culture-medium for the germs to acquire virulence in and entail serious complication. His extensive experimentation has established the fact that animals kept fasting, recovered far more rapidly and without complica-

tions from acute infections and severe traumatism, than others in the same conditions, fed as usual or even much less than usual. He forbids all food to his patients in acute infections, especially in pneumonia, if there is any reason to suppose that the digestion will not proceed normally. Observations of 140 cases of pneumonia have confirmed the wisdom of this course, which has won for him the name of the "starving doctor." In every case it was noted that during the prolonged fast, sometimes a week in length, the patient partially regained the strength he seemed to have entirely lost before. De Renzi "also places fasting in the front rank of the remedies for arthritism."—*Gaz. d. Osp. e d. Clin.*, February 6.

A Simple and Radical Treatment of Hydrocele has been followed by O. Bloch of Copenhagen for several years, in forty cases, which is effective, radical, painless, and allows the patient to resume his usual occupation almost at once. After chloroform, the scrotum is incised sufficiently to disclose the testes completely. The tunica vaginalis is then turned back its entire extent, excrescences on its internal surface removed, and this entire surface energetically frictioned, even into its remotest crevices, as also the surface of the testicle, with sterilized gauze impregnated with 3 per cent. phenicated water. The phenic acid coagulates the albumin in the epithelium of the serous membrane, so that it ceases to secrete liquid. The testicle is then reduced, the serous cavity tamponed with a strip of gauze, left protruding, and a simple anti- or aseptic dressing applied. Three or four days later the gauze is removed and the wound sutured, including only the skin, and the patient dismissed with a simple suspensory to be worn for a while. All his patients have been examined recently, the time that has elapsed varying from eight months to five years. Only one case relapsed. In this the hydrocele had existed two years, and was as large as a child's head and so painful that the frictioning was less thorough than usual.—*Revue de Chirurgie*, February 10.

The Cataract of Glass-Blowers.—J. Hirschberg in the *Berliner klinische Wochenschrift* comments upon the connection between cataract formation and occupations entailing exposure to intense heat as well as residence in hot climates, as having been long recognized. He contrasts the early age of the glass-blowers so affected with the late visitation upon the subjects of senile cataract. This difference, the writer says, ranges from forty years in the former class to that of sixty years in the latter. The heat exposures in India yield similar results of what might be styled as traumatismal. The late Dr. C. R. Agnew of New York was wont to cite cooks and stokers as his classical examples, but claimed that glare rather than heat was responsible for the result. Also in the ante-specialistic days, Dr. Willard Parker gave the dark-eyed as the preferred victims and females as the more constant sufferers. Thus there was no lack of observers although on somewhat divergent lines. Racial peculiarities of the darker skinned with their more torrid environments and heated apartments, with the eye strain of sewing, minute writing, etc., may be in reality the secondary developers. In this connection a well-known ophthalmologist of the Atlantic slope unhesitatingly maintains that but few over fifty years of age can be said to be immune from the cataract disqualification. To his mind the question, one of degree solely, belongs to the domain of prognosis rather than that of diagnosis. Might it not be said that the centrifugal influences inherent in all animals operate in the eye uniformly with the determination of pigmentary and like deposits to the surface? The phenomenon is most readily observed in transparent media and at the points of least resistance. The elaboration of the theory, however, is rather vague and better classifications may be more instructive in what are rated as the higher circles of civilization. Until then hygienic preventives will avail but little, although investigations are exceedingly fascinating. At all events let our statistics be free from prejudice and hasty conclusion.

Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	\$.50
Foreign Postage	1.76
Single Copies	10 Cents.

In requesting change of address, give *old* as well as new location.
Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, APRIL 2, 1898.

THE DIAGNOSTIC VALUE OF LUMBAR PUNCTURE.

The operation of lumbar puncture, which has now been before the medical profession for some years, is now perhaps beginning to drop out of sight, or at least to be less prominent in medical literature than was the case two or three years ago. It is not meant by this to say that it is becoming obsolete or that all interest in it has been lost, for certainly that is not the case, but the zeal with which it was at first taken up has somewhat lessened as the novelty diminished with time and the claims of its therapeutic efficiency became less prominent. That it has not met the expectations of its advocates as a remedy for cerebro-spinal pressure in various conditions where it is abnormally increased seems to be a fact, notwithstanding the testimony as to its effectiveness in certain cases by very high authorities. That on the other hand it is coming to be recognized as a valuable diagnostic aid, is also true, and evidences of its worth in this special regard are still being multiplied. That, under proper antiseptic precautions, it is a perfectly safe procedure or so nearly such as to meet all reasonable objections on that score, may also be accepted as a demonstrated fact. Where the need of diagnostic data is clear and there is no substitute method of equal value available, there is no reason why this procedure should not be resorted to and only blame can attach to its neglect. In all forms of cerebral disease that are accompanied with pressure or irritative symptoms there is a possibility that lumbar puncture may afford revelations of the highest diagnostic importance and in some instances it almost alone can give the needed information. This is true more especially in dubious

cases of meningitis where the symptoms may indicate possibly other conditions that would modify the prognosis and the treatment. In other respects it may also be of value as showing the presence in the cerebro-spinal fluid of various bacterial forms, tubercle bacilli pneumococci, staphylococci, etc. Altogether the introduction of the method has been, beyond question, an advance in both a practical and scientific point of view as regards diagnosis, whether or not it has any actual or considerable value as a therapeutic resource.

While lumbar puncture may often afford positive evidence of inflammatory conditions or the presence of irritative germs within the meninges, there is still a question sometimes whether, in the lack of positive proof, we can exclude these conditions from a negative finding in the operation. It is generally admitted that a turbidity of the cerebro-spinal fluid indicates meningeal disorder, but does a perfectly clear condition exclude it? This question is discussed at length by Dr. ARTHUR SCHIFF in a recent paper in the *Wiener klinische Wochenschrift* in which he exhaustively reviews the German literature of the subject. He finds that, according to numerous observations by QUINCKE, LICHTHEIM, FUERBRINGER, LENHARTZ and others, that while a turbid fluid is a certain sign of meningitis, which may be of tuberculous or other origin, a complete limpidity may coexist with various non-meningitic disorders (tumor, abscess, saturnism, chlorosis, etc.) and also with tuberculous meningitis itself and that therefore it can not be accepted as an adequate diagnostic sign of the absence of this affection. It may also be clear, however, with an encapsulated purulent meningitis, and apparently also, according to some observations, turbidity may be lacking in some cases of more generalized purulent inflammation. A negative finding in this regard can not, therefore, be accepted as absolutely conclusive as to the presence or absence of any generalized infectious process in the meninges.

Dr. SCHIFF in his communication calls attention to still another point which may be of diagnostic value in these cases, viz., the coagulability of the cerebro-spinal fluid. According to LICHTHEIM this feature of coagulability is present in all cases of purulent or tuberculous meningitis, and his opinion is supported by the observations of QUINCKE and SCHIFF, the latter going so far as to say that lacking this symptom we may correctly diagnose a non-meningitic condition. The fact that it has been neglected to a large extent as a diagnostic point is a little noteworthy under the circumstances. There may be exceptions, possibly, to the rule, and his view may be a little too positive, but from the data he gives from his own observations and those published by FLEISCHMANN it would appear that we have in this point of the coagulability or of the non-coagulability of the cerebro-spinal fluid a very important diagnostic aid, of special service when it is

desired to ascertain whether or not there are meningitic complications that may affect the prognosis of an otherwise indicated operation.

The operation of lumbar puncture is one that is not to be too recklessly resorted to, but as already stated, when other diagnostic methods are insufficient and it is important to ascertain the facts of a suspected general meningitic inflammation, it may afford data of the utmost value. As a therapeutic method its utility appears to be, if not altogether dubious, at least a limited one.

THE DIAGNOSIS OF ARTERIAL, MENINGEAL AND CEREBRAL DISEASE DUE TO SYPHILIS.

There are few problems in neurology which puzzle the specialist and the general practitioner more than the differential diagnosis of intracranial disease due to syphilis, except the symptoms be peculiarly frank and well developed. The difficulties in the case are also often greatly increased by the absolute denial on the part of the patient that he has ever been a victim of this specific infection, a denial which may be conscientiously made, for it is to be remembered that nervous syphilis often develops in persons many years after the primary infection and without any intermediate secondary lesions. Further than this it is not to be forgotten that syphilis may be innocently acquired, although such cases, in males at least, are rare.

The symptoms of intracranial syphilis closely resemble other forms of cephalic lesion and are doubtless often considered as true or simple meningitis, thrombosis or hemorrhage, yet a diagnosis of their specific origin, if made, will open possibilities of relief to the patient which are not to be considered when the results of non-syphilitic lesions are discussed. After advanced tissue changes are developed, even if their cause be syphilitic, curative treatment is largely unavailing, but before the pathologic process becomes hopeless great relief can be afforded by medical treatment. A very interesting and useful clinical paper has recently been written by TEISSIER and ROUX, in the *Archives de Neurologie*, for January and February 1898, on this topic, in which they consider, in an exhaustive manner, the differentiation of the various forms of syphilitic brain troubles such as arteritis, meningitis and gumma. It is evident that such a differentiation must be in many cases impossible, because it is not an uncommon occurrence for all these changes to be present in a case at one and the same time, but on the other hand if they be present singly these authors believe that they can be diagnosed with some certainty.

In regard to syphilitic cerebral arteritis it is a noteworthy fact that the symptoms of malnutrition of the nervous tissues are well developed, for the paralysis when it comes on is usually of the flaccid type with

loss of the reflexes; and hemiplegia, or more often monoplegia, with partial involvement of groups of muscles, is the condition of the patient. TEISSIER and ROUX believe that these symptoms in a non-hysterical and previously healthy individual are very pathognomonic. Headache is comparatively rare, is diffuse, and not produced by pressure or tapping the vault of the skull, but there may be perverted sensation as of numbness of a limb or formication as prodromes of the onset of the paralysis just named. Optic neuritis is rarely seen in syphilitic arteritis although syphilitic lesions of the retinal vessels may be evident. Ocular palsies are rare and arise from secondary lesions as by the pressure of an aneurysmal growth on the nerve involved. The intelligence usually fails gradually, due to the impaired cerebral nutrition, and if any mental strain is present may rapidly give way for this reason. Transitory aphasia is an important symptom and is often associated with paralytic symptoms of one side of the face and of the right arm. Very rarely, when the arteritis has developed so far as to result in a thrombus with secondary degenerative changes in the pyramidal tract, the paralytic symptoms just named are spastic instead of flaccid.

When the specific poison attacks the meninges, however, the train of symptoms is quite different from that just described, for now the signs instead of being those of feebleness and atony are those of excitement and irritation. The paralyzes are spastic, the reflexes are apt to be exaggerated, partial epileptiform attacks are frequent and the muscles affected are more numerous than when arteritis is the cause of the trouble. Headache is diffuse and constant and so severe as to cause delirium or suicidal tendencies and, unlike that due to arteritis, can be increased by pressure or light blows on the skull. Darting pains in the limbs may be present and areas of paresthesia, anesthesia or hyperesthesia are frequently found. These symptoms are not transitory as in arteritis, but persistent. Then again, optic neuritis, loss of pupillary reflex due to compression of the optic tracts with homonymous hemianopsia or amaurosis from this cause or sometimes bitemporal hemianopsia from pressure on the chiasm are to be found. The aphasic symptoms, which in arteritis are so fleeting, in meningitis are more permanent, and maniacal delirium may occur, but in the same periods the intellect is not greatly enfeebled. When the inflammatory process in the meninges is acute and at the base of the brain, vomiting, paralysis of the cranial nerves and bulbar symptoms are present, and death comes in coma. If it be limited to the convexity of the brain noisy delirium, convulsions and finally hemiplegia or monoplegia with coma are present. When the condition is chronic the symptoms are more slow in onset but otherwise similar to those just described.

We must not forget that in some instances, as we have already stated, the combination of arteritis and meningitis or the presence of secondary vascular changes producing thrombosis with degeneration or pressure by aneurysmal growths may result in a mixture of the symptoms already detailed, and again that syphilitic pachymeningitis hemorrhagica with symptoms of cerebral hemorrhage may be present.

In syphilitic gumma of the brain choked disc is usual, hallucinations rare, distinct focal paralysis is common and headache is apt to be localized. The cranial nerves are paralyzed only if the growth is so situated as to press upon them, and the temperature is very rarely febrile, whereas in meningitis it is often raised.

THE DISSECTING ANEURYSMS OF THE HEART.

In our issue of March 12 (p. 626), we invited attention to the recent Memoir¹ of Dr. ARTUR VESTBERG concerning the pathologic anatomy of the dissecting aneurysms of the heart, from which the following interesting facts are abstracted.

As the result of these researches it has been established that there exists in the human heart a form of aneurysm which, because it is more or less analogous to the dissecting aneurysms of the vessels, may be quite properly designated as dissecting aneurysm of the heart.

The author defines a dissecting aneurysm of the heart as a pathologic cavity communicating with the heart itself or with the origin of the aorta, due to a separation by the pressure of the blood of the layers of tissue composing the walls of the heart.

The affection occurs in the four following varieties:

1. The parietal form, where the cavity of the aneurysm is situated between the layers of the free external walls of the heart.

2. The septal variety, where the aneurysm is situated in the wall of the interventricular or interauricular septum.

3. The valvular variety, in which the cavity occurs between the two lamellæ of a cardiac valve.

4. The interparietal variety, which occurs between the exterior surfaces of the walls of the various heart cavities, which normally are united by loose cellular tissue.

The last variety of dissecting aneurysm of the heart is the most common, and it occurs in the space which the author calls the peri-aortic space of the heart. As far as known this space has not been thoroughly described as yet. It is a subepicardial cellular space, the periphery or external wall of which is formed in part by the anterior wall of the auricles, in part by the *conus arteriosus dexter*. Its internal or central wall is formed, first by the lowermost part of the wall of the aorta; second, underneath this by the root of the aorta, which belongs to the heart according to its struc-

ture and which carries the attachments of the valves, under which again are formed the intervalvular spaces of Henle; third, by an inconstant parietal strip situated between the root of the aorta above and the fibrous zone of the mitral valve and the interventricular septum below; this strip should be considered as the wall of a *conus arteriosus sinister*. A loose cellular and adipose tissue fills the space mentioned.

A rupture of the central wall of this space, either from the left ventricle or from one of the sinuses of Valsalva, would allow the blood to penetrate into the space and the force under which the blood is confined would separate the walls one from the other and lift up the roof of the space, which is formed by the epicardium, and thus establish a dissecting aneurysm in all or part of the peri-aortic space. This then is the interparietal dissecting aneurysm of the heart.

From the peri-aortic space the blood could penetrate further between the leaflets of the ventricular septum or of the auricular septum, circumstances which render it impossible to separate precisely the interparietal dissecting aneurysms from the dissecting aneurysms of the septum. There exists on the other hand, transitions of the interparietal aneurysms to the parietal aneurysms, in that the peripheral wall of the space mentioned is interrupted by the coronary arteries, and here an aneurysm of the peri-aortic space could penetrate between the epicardium and the myocardium of the free external wall of the heart. The orifices of the coronary arteries separate that part of the peri-aortic space which is limited by the *conus dexter* from the part which is limited by the wall of the auricles.

The actual case which leads the author to study this interparietal form of dissecting aneurysm of the heart concerns a woman 32 years old who died from the consequences of chronic and acute ulcerous endocarditis. There was a partial rupture of the central or internal wall of the space, between the aortic valves (the posterior valve and the left valve), that is, at the base of the anterior mitral valve, with the formation of a dissecting aneurysm in the auricular part of the space. The aneurysm was of long standing, and had acquired a well marked secondary or new wall.

The author has collected from the literature fifty-nine cases of dissecting aneurysm of the heart, of which he gives a summary. Including his own case the total number becomes sixty. Forty-seven of these were interparietal or septal. It has already been said that it is impossible to separate precisely the one from the other. A few of these also presented partial transformation to the parietal type. Five aneurysms were parietal and eight valvular.

Among the interparietal cases the aneurysm occupied in twenty-five cases the auricular part; in thirteen the part of the cone, and in eight cases it was not possible to make special localization.

¹ Om dissekerande hjärtaneurismer, Nordiskt Medicinskt Archiv, Nos. 26 and 30, 1897.

Excluding the valvular cases the point of departure was one of the cavities of the heart in thirty-one cases, the left ventricle being the one involved in all the cases except one of parietal nature, which appeared over the right auricle. In sixteen cases the aneurysm took its origin from the sinus of Valsalva.

The cause of the lesion which allowed the blood to pass between the tissues composing the walls of the heart was in most cases an endocarditis, generally of an acute ulcerous nature. Sometimes an abscess appeared to have been preformed in the cavity of the aneurysms. In other cases the solution of continuity was produced on account of atheromatous changes in the aorta or by rupture of an ordinary aneurysm. In two cases the primary rupture was probably traumatic.

The interparietal aneurysms frequently present the form of a pouch, but they may occupy the larger part of the space, and then they take the form of the space. When the aneurysm is situated in the ventricular septum it can, exceptionally, become directed toward the cavity of the right ventricle, but it appears more often to cause a diffuse separation of the two leaflets of the septum toward the ventricular cavities. Sometimes this separation may extend throughout the entire extent of the septum.

The form of the opening of the aneurysm may be linear, especially when it is caused by rupture, or it may offer a more rounded form when the perforation is due to ulceration.

Aneurysms in the early stages naturally lack an independent wall, but in the chronic cases there is formed a secondary membranous wall. Frequently the contents are thrombotic.

Secondary rupture of the aneurysms occurs. Very often the rupture takes place into the cavities of the heart, causing abnormal communications between them. Very rarely the aneurysm ruptures into the pericardium.

Among the valvular cases two originated in the valves of the aorta, starting from the lumen of this vessel. Two were formed in the septal curtain of the tricuspid valve, and four were formed in the anterior mitral curtain.

THE DIFFERENTIATION OF THE ANEMIAS.

Not many years ago, physicians were as much accustomed to declare a patient "slightly anemic" as to ascribe the symptoms of another unfortunate to "a touch of the malaria." As we know that the latter disease exhibits different varieties and a vast number of anomalous symptoms, and that we are justified in making a diagnosis of ague only after finding the plasmodium in the blood, so we have learned that in anemia there are many forms whose symptoms are so similar that they can frequently be recognized only by most careful hematologic examination.

A thorough and systematic examination of the blood involves more time and skill than that of any other tissue of the body. Before one has accomplished such a feat he must have examined the fresh blood, dried and stained covers, counted the red and white corpuscles, estimated the amount of hemoglobin, the relative volumes of corpuscles and fluid portion of the blood (by means of the hematocrit), taken the specific gravity, and finally must have made a bacteriologic examination. In many cases an accurate diagnosis can be reached with but a small number of these steps, as for instance in malaria. The first "fresh" slide may reveal large numbers of the plasmodia, and as these parasites enter the substance of the red corpuscles causing their destruction, we would expect to find an accompanying anemia. But it is often of advantage to know the degree of corpuscular destruction. This can only be done by a count of the red cells. In certain of the infectious diseases the white elements of the blood are increased, in others diminished, while the reds may be considerably diminished in either. This difference in leucocyte count has often been of use in differentiating acute miliary tuberculosis from typhoid fever. Again, enough evidence may have been found to account for a simple anemia, but the patient not responding to appropriate treatment, a more extended examination may show that the disease is of the pernicious type. This specific gravity estimation is a method intending to replace the hemoglobin estimation with the Fleischl hemometer, while the hematocrit is offered as an apparatus by means of which the number of corpuscles can be approximately determined with rapidity. Bacteriologic examination in cases of suspected septicemia and pyemia is of evident value.

Now as to the anemias themselves. Too often this much abused expression is applied only to a lack of the red corpuscles, and the diagnosis is reached by a cursory glance at the roof of the mouth, the lips, or the conjunctivæ. Properly an anemia embraces much more than the above. It is a lessening of the whole quantity of blood, or of any of its more important constituents. A diminution in the amount of hemoglobin or of albumin might be correctly regarded as a variety of anemia. In classification one would first look at the grade of the anemia, best expressed by the number of the red elements. Secondly, it should be ascertained whether the anemia is accompanied by an increase or diminution in the number of the white cells—a leucocytosis or a leucopenia—and if leucocytosis, whether it is of a high or low grade. By means of the Thoma-Zeiss instrument, the number of red corpuscles in a fixed unit of volume (one cubic millimeter) is stated approximately in the male as 5,000,000, in the female as 4,500,000. Assuming that the red only are at fault, by putting a dividing line at 1,200,000, we make our first attempt at classifica-

tion; an anemia at or below this is of the primary or pernicious type (except after severe hemorrhage). However, the disease in question may be pernicious anemia, and yet the blood count be greatly above our dividing line. The secondary types, simple anemia and chlorosis, practically never have a count below 1,200,000. Therefore there may be cases in which a blood count would not distinguish between pernicious anemia and simple anemia and chlorosis. In simple anemia the hemoglobin is diminished *pari passu* with the loss in red corpuscles, for example, a count of 4,000,000 (in a male) will give 80 per cent. of hemoglobin, while in chlorosis the percentage is greatly lessened as compared with the count. A hemoglobin per cent. of 35 with a count of 4,000,000 is not an unusual conjunction. In pernicious anemia the hemoglobin is always below normal, yet when compared with the number of red corpuscles, it is apparently greatly increased. This comparison determines the so-called color index. Suppose a case with a blood count of 1,000,000 has a hemoglobin percentage of 30; if we could increase the count to 5,000,000, the hemoglobin would be raised to 150 per cent. Our color index in this case would then be one and a half. By these two methods of examination we would often be able to differentiate pernicious anemia, but other evidence should be obtained from stained specimens. In a slide from a case of pernicious anemia, probably the first point to attract attention is the variation in the size or shape of the red corpuscles. In many the disc shape is lost, and in those that retain it we may find corpuscles two or three times the diameter of their immediate neighbors. This is known as poikilocytosis and is extremely common in this disease. Another point evidenced is that of so-called polychromatophilia. Here, neighboring corpuscles show considerable variation in color. This reaction is best brought out with the triple stain, and is due to the fact that many of the reds, which normally respond only to the orange have taken on an affinity for the other colors of the mixture. Continuing, nucleated reds are seen, of two classes, the normoblasts, and the megaloblasts, giant forms with immense purplish or greenish nuclei. The latter are separated from the surrounding protoplasm by a narrow white (unstained) ring, are regarded as reversions to the fetal type and are found but rarely in other affections and then in small numbers. In hematology, however, we may make the diagnosis of pernicious anemia on this one finding: when the megaloblasts exceed in number the normoblasts.

To summarize our findings of pernicious anemia: we have reds, about 1,200,000 or less per cubic millimeter, high color index, poikilocytosis, polychromatophilia and megaloblasts increased over normoblasts.

The second division of the anemias is that charac-

terized by a diminution in the reds plus the presence or absence of a leucocytosis. A lessening of the red may be accompanied by a diminution in the white corpuscles, as occurs in malaria and typhoid. Therefore we may have a red corpuscular anemia accompanied by a leucopenia or diminution of white cells, as in pernicious anemia; a normal number of whites as in simple anemia, chlorosis and Hodgkin's disease; a leucocytosis of low grade, as in sthenic pneumonia; and lastly, a lessening of the reds with a leucocytosis of high degree, as in the leukemias. The latter are divided into two varieties, the spleno-myelogenous and the lymphatic. Pure splenic and myelogenous types do not exist. Both forms of leukemia have an anemia of about equal grade (3,000,000), and a large permanent leucocytosis. In the spleno-myelogenous, a ratio of one white to ten reds is common, and the ratio may be one to two; in the lymphatic variety the ratio is about one to forty, rarely exceeding one to ten. A leucocytosis rarely exceeds 1,000,000, or a ratio of one to fifty. The greater the leucocytosis, the greater is the anemia. Another point in distinguishing the two varieties of leukemia is a marked change in the ratio of the different forms of the white corpuscles one to another. In the lymphatic variety the leucocytes are nearly all young forms, called lymphocytes, while in the spleno-myelogenous, though all forms are absolutely increased, relatively they are all diminished (except the eosinophiles), and 35 to 40 per cent. of the leucocytes is taken by a cell found, normally, only in the marrow of bone. This myelocyte is a white cell of large size, distinguished only from the large lymphocyte in possessing granules, and from the neutrophiles by the shape of its nucleus.

Hodgkin's disease has always been a stumbling block in the study of the blood. It resembles some cases of leukemia and the blood examination is always a surprise. There is no anemia, the size of the reds is normal, none are found nucleated, the leucocytes rarely exceed 7500, and the ratio between the different varieties of whites is normal. The differentiation of amyloid disease, chronic malaria and chronic interstitial nephritis, from pernicious anemia is more difficult. This always requires a considerable search of stained specimens before a satisfactory conclusion can be reached. Special stress is put upon this method of examination, for the more one studies stained specimens the more reliance will be put upon their findings, especially when the Ehrlich stains are employed.

THE WEEK IN CONGRESS.

The return of Mr. GALLINGER from the Isle of Cuba has apparently given new life to the CAFFERY bill in the Senate, and also to the Antivivisection bill.

Mr. CAFFERY addressed the Senate in favor of his bill on March 22, and again on March 23, and accord-

ing to the *Record* spoke over two hours on the first occasion, and nearly two hours on the second occasion. No other speeches have been made on the subject, and his own speech has not been printed, as he has not yet concluded.

Senator SPOONER has further amended his bill, and will press the amendment when it comes up. The great and overwhelming interests of our country in the Spanish imbroglio and fiendish assassination of our sailors in Havana harbor have prevented consideration of the sanitary matters to the extent that otherwise would have been given them.

Our friends should continue their efforts against the CAFFERY bill, as although last week it was supposed to be "snowed under."

The Medical Department of the Navy have succeeded in having the age limit bill (Senate 2872) passed. This bill provides that the revised statutes which now fix the age limit of persons to be appointed Assistant Surgeons at 26 years, at 30 years, so that hereafter the section will read: "No person shall be appointed Assistant Surgeon until he has been examined and approved by a Board of Naval Surgeons designated by the Secretary of the Navy, nor who is under 21 or over 30 years of age." The twenty vacancies in the Medical Corps of the Navy will be speedily filled when the House passes this bill. The age limit of the services, as it now stands is, Navy 26 years, Army 28 years, and under the regulations of the Marine-Hospital Service, approved some years ago, the age limit in that civil service was fixed at 30 years. The wisdom of this was evident by the fact that there is never any trouble in filling existing vacancies, whereas in the Navy Department they have always had difficulty in securing persons under 26 years of age who could pass the required examination. It is to be hoped that the House will take this bill from the speaker's table and pass it without delay, as owing to the rapid increase of the new Navy it is necessary to have these vacancies filled as soon as possible.

CORRESPONDENCE.

An Open Letter.

Read before the Boston Medical Society, March 15, 1898, by R. K. Noyes, M.D., and unanimously approved and adopted by the Society, and recommended for publication.

To the Trustees, the Superintendents, the Staffs, and the Medical Officers of the Hospitals and Dispensaries of Boston.

Dear sirs and gentlemen:—The members of the Boston Medical Society feel constrained to present for your respectful consideration certain facts and conditions, which seem to have an intimate relation to the construction and to the solution of the problem which is known as the "abuse of medical charity."

It is hardly necessary to say that the problem in question, which, at the present time, so frequently comes to the attention of the medical profession in all large centers of popula-

tion, has, on the one hand, features which are perplexing as well as delicate, and, on the other hand, features which are nevertheless exasperating and disheartening.

We deem it proper to state, not without due regard to the fitness of things, that we have hoped for a long time, that the initiative in the matter of dispensary-abuse reform, would be taken, and that an adequate remedy for the evil would be discovered and applied, by some action on the part of the Massachusetts Medical Society. And we beg to believe that it will be readily agreed by all fair-minded medical men, that we had, in that able, honored and influential body, the most ample and justifiable grounds for so hoping, as well as supposing and expecting, inasmuch as it is from within that Society that our vaunted medical ethics, which determine, not only our relations to our professional brethren, but also our relations to the public in general, are supposed to originate.

Moreover, it is from the members of that Society that our medical colleges frequently obtain their tutors, instructors and professors, and that our hospitals choose their medical and surgical staffs: and it is toward those members of the profession that there is always the strongest tendency on the part of practitioners to hold sentiments of special honor, and to feel inclinations for emulation.

It is with pleasure that we acknowledge the almost uniform courtesy, generosity, sympathy and fairness, which eminent professors, both as private practitioners and as consultants, have accorded to us.

As against the professional ethics of the consulting practitioners of Boston, or of the staffs and medical officers of the hospitals and dispensaries, in our professional relations with them, especially in emergent and capital cases, we have no inclinations to complain and no reasons to protest.

But, as private practitioners, we have had, with no slight feelings of regret, occasion to experience what seems to us an entirely different condition of things, as manifested in the methods which are employed by some of the medical men, who are connected with the medical and surgical out-patient departments, in the several large dispensaries, in their relations to us as professional brethren, and in their relations to certain dispensary patients, especially to those patients who were ours perhaps a day, or an hour, or a year, previously, and who would otherwise be ours continuously, when occasions require, if only the same principles of medical ethics were carried out by these gentlemen in public practice as they would undoubtedly carry out in their relations to us in private practice.

As to medical consultations in general, aside from the special welfare of the patients, two things are always of particular importance, as between the practitioner and the consultant, namely: first, that the former shall remain in full charge of the patient, and second, that he shall have his standing with his patient enhanced and fortified. Therefore, that this is not done in our large dispensaries, is precisely what we allege against certain medical men and medical officials, who practically have charge of the conduct of all the principal dispensaries in Boston.

However unwittingly dispensary physicians and surgeons may be responsible for it our complaint is that, by giving advice and treatment to patients at the dispensaries, many of whom must be assumed to be able to pay for it, without a note of request or of recommendation from their family physicians, except in emergent cases, and by omitting to uphold the ability, the proficiency and the procedure of these family physicians with reference to all cases, so far as may be consistent with fact and with conscience, which as to most all dispensary patients can be truthfully done, we not only lose through them our patients but also we lose our standing with our former patients, and hence our standing with prospective ones and with the public.

Even if that result arises, as possibly may be the case, from a purely negative attitude toward the patients and the public

and toward the profession, it hardly needs to be pointed out as to what the consequences would be if that same negative attitude were to be assumed by them in the ethics which would govern them as honorable private practitioners, or especially in their capacities as private consultants with any physician among us, were the opportunity offered to them to do so.

Ethically, as well as justly, it certainly can not be held by any physicians, nor should the public be led to believe by any words or acts on the part of medical officials or dispensary practitioners that private practitioners in general, who are instructed by these same professors, who are graduated from the same colleges, who possess the works of the same authorities, who employ the same therapeutics, who proceed upon the same theories, who have as good a practical experience, who realize as great a sense of responsibility, and who evidently are inspired by as high an ethical sense, are less competent professionally or less successful with given cases than many of those physicians and surgeons who are officially connected with the dispensaries and with the out-patient departments of the hospitals.

In the position from which we take our observations, it may never have come to the attentions of the gentlemen to whom we in this letter especially address ourselves, that, according to the unchanged intentions of those institutions in question so far as can be shown by the statutes and by the original parchments, there is no provision for any such perversion of the conduct of the dispensaries of Boston as seems to be clearly demonstrated by the manifest tendency of some of the dispensary physicians to utilize in their official capacities the dispensaries and the out-patient departments of the hospitals, for something other than the disinterested welfare of the sick poor, and of the official management of the dispensaries to protect and to promote the existence of these institutions by any such means as the dispensing of drugs and of medicines for remuneration.

In conclusion, it is only desirable to add as to the work of medical charity that, as citizens and as physicians, we desire to declare and to emphasize our earnest advocacy of free dispensaries for all those persons as designated in the hospital and dispensary charters who are sick, poor and unable to be properly treated and cared for at their homes and to pay a physician, and that such persons should not be deprived of the blessings and the benefits of such dispensaries by the unjust encroachments of the well-to-do, the well dressed, the selfish and the fraudulent, and that as private practitioners who constitute the great body of the medical profession, and who traditionally are known to be self-sacrificing and to be ever generous toward the needy and the humble, we shall, so far as may be consistent with our time and strength whenever proper occasions arise, endeavor to give cheerfully our professional services without remuneration to all those whom we may personally know to be in need and to be deserving thereof. Signed for the Society,

M. GERSTEIN, M.D., Secretary.

The Free Medical and Surgical Treatment of the Well-to-do in Michigan University.

CHICAGO, March 24, 1898.

To the Editor:—I am very glad to see Dr. Vaughan's statement of the policy of the Board of Regents of Michigan University with regard to the admission of patients able to pay for treatment to the free clinics of their medical department. It would be well for the credit of the University of Michigan, whose faculty and teachings we all respect and admire, that this statement should be given the widest publicity not only among the profession at large, but also among the members of their teaching corps: because the ideas entertained by the writer of the editorial corrected by Dr. Vaughan, are very widely entertained. Last summer, your correspondent was discussing

with one of the clinical instructors of the University, the clinical advantages to be found in Ann Arbor (we were *not* discussing the abuse of medical charity), and he spoke of the very large number of patients there from all parts of the State and mentioned incidentally, that many of them had no business in a free clinic; but said that they were not allowed to refuse treatment to any citizen of Michigan however wealthy. He said he sometimes puts off operating on well-to-do patients on one excuse and another, till they get tired and go elsewhere, but that he is never permitted to refuse them outright. This particular member of the faculty and doubtless others, will be glad to be corrected.

Very respectfully,

HORACE M. STARKEY, M.D.

Treatment of Pulmonary Tuberculosis.

SANTA CLARA, CAL., March 22, 1898.

To the Editor:—I am well pleased with the results of my letter on "Oxytuberculin," published in *The Journal*, Feb. 19, 1898, p. 446. It is bringing out much more in the way of facts than I could have hoped for.

I am obliged to Dr. Beattie for the information that seven physicians out of 120 *regular* physicians in the county have used "oxytuberculin." I presume that the "(or more)" which follows the "seven," may be assigned to the forces of the *irregulars* until the "(or more)" materialize. I think that it argues remarkably well for the intelligence of the profession of this county that only seven physicians have been credulous enough regarding "oxytuberculin" to use it, especially when living within but a few miles of the place of its production.

In regard to the case of asthma alluded to in my letter, I will state for Dr. Beattie's benefit that I am in possession of more facts than he gives me credit for. However, it is not the purpose or scope of this paper to state how I know these same facts.

In the San Francisco daily *Examiner*, Monday morning Oct. 25, 1897, p. 2, appeared the following paragraph: "Dr. D. A. Beattie of Santa Clara, has used Dr. Hirschfelder's cure, and this month he reported its effect on a patient. He said that at the beginning of the treatment the patient was not expected to live a week, but now appears perfectly well." Evidently "cured" does not mean the same as "perfectly well" in Dr. D. A. Beattie's way of thinking, or there is a mistake somewhere.

There is no doubt about the patient referred to by me having asthma. The patient still has asthma. The fact that the patient may have caught cold and had sub-acute bronchitis will account for the symptoms observed in the case, but does not constitute positive evidence of tuberculosis. The fact that the patient is much better now and remaining so through the winter and spring months is evidence that the patient in all probability has no tuberculosis. Dr. Beattie has confirmed my knowledge of the case by acknowledging that the patient has asthma. "The case was far gone," Dr. Beattie says. Dr. Hirschfelder does not recommend his oxytuberculin as a cure for advanced cases. I think I am fully justified in doubting the diagnosis of tuberculosis in this case. I am also inclined to the belief that the Doctor has not kept a close count on the number of paroxysms of asthma recurring in this patient during the past fifteen months. I am credibly informed that there have been many more paroxysms of asthma in that time.

I will agree with Dr. Beattie that in some of his cases there was marked evidence of tuberculosis. I am not aware of any of them having been materially benefited by oxytuberculin. Some of these cases have terminated fatally.

I will agree with him that "facts are better than statements." That is just what I hope to make clear before I am done with this subject.

I am glad that Dr. Beattie acknowledges that he can not guarantee a cure of tuberculosis in any case. We had surmised that the Doctor felt equal to the task of curing many if not most cases of tuberculosis he might encounter.

I must thank Dr. Beattie for the statement that "his own experience" will not lead him to "say that oxytuberculin will cure a single case of tuberculosis." He coincides with the majority of the medical profession in that regard. There is never a contra-indication toward applying any remedy which will relieve distressing symptoms. I fail to understand what he calls a "specific treatment." I think no remedy can properly be classed as a specific until it will positively and permanently cure a fair per cent. of a particular sort of cases.

Yours respectfully, E. H. SMITH, M.D.

Grand River Valley Medical Association.

HOLLAND, MICH., March 28, 1898.

To the Editor:—On page 739 of the JOURNAL, March 26, 1898, under the head of "Post-Graduate Lectures at Home," it is claimed Eastern medical societies have adopted a new plan by which they increase their membership and interest in the meetings. The Grand River Valley Medical Society of Michigan adopted this plan in 1894 when at their annual meeting Prof. J. H. Etheridge was invited to be with us and read a very instructive paper; since which time we have had such men as Professors Dock and McClintock of Ann Arbor, Professors Graves, Green, Boise and Griswold of Grand Rapids. We find our meetings are made very instructive by this plan and will continue it as long as we can procure volunteers for their expenses and entertainment. Will some Chicago men volunteer for our May and August meetings, which occur on the second Tuesdays of those months?

B. B. GODFREY, M.D., Sec.

Why Not the House Cat?

LANSDOWNE, PA., March 2, 1898.

To the Editor:—I have been interested in the letters regarding the castration of squirrels, in the March 5 issue of your excellent JOURNAL, and it occurs to me to suggest that some learned member of the profession set himself to the bringing out of some scheme whereby the squirrels might be led to teach their progeny-limiting process to the common house cat! In the interest of peace and quietness and sweet refreshing sleep, such an happy "artificial cut-off" as Saxe says, is needed. Fame and fortune await him who will bring to pass this step toward Heaven.

Sincerely, J. M. LAURISON, M.D.

ASSOCIATION NEWS.

Section on State Medicine.—The following additional papers (*vide* JOURNAL, March 26; p. 743), for this Section:

The Importance of the Immediate Sterilizing of Foods and Drinks before their Ingestion, by Augustus P. Clarke, Cambridge, Mass.; Henry D. Holton, Brattleboro, Vt., will open discussion.

Relation of the Courts of Lunacy Law or Insanity Before the Law, by Charles H. Hughes, St. Louis, Mo.; discussed by William P. Munn, Denver, and T. D. Crothers, Hartford, Conn.

The Milk Supplies of Cities, is the Public Entitled to Receive Better Service? by Henry O. Marcy, Boston, Mass.; discussed by Henry L. Coit, Newark, N. J.

Some of the Duties of Health Boards, by Henry D. Holton, Brattleboro, Vt.; discussed by Charles H. Shepard, Brooklyn.

Alcoholic Stimulation or Irrigation, Which? Including their Uses and the most Efficient means to Obtain their Effects, by W. Van R. Blighton, Buffalo, N. Y.; discussion opened by J. H. Kellogg, Battle Creek, Mich.; Charles H. Hughes, St. Louis; T. D. Crothers, Hartford, Conn.; Augustus P. Clarke, Cambridge, Mass.

The following have promised papers but subjects have not yet been received: Benjamin Lee, Philadelphia; H. N. Avery,

Minneapolis, Minn.; Lewis D. Mason, Brooklyn; Thos. F. Harrington, Lowell, Mass.; Elmer Lee, New York City.

Section on Cutaneous Medicine and Surgery.—The Section on Cutaneous Medicine and Surgery (and this includes syphilology) promises to be a useful and interesting meeting. The chairman of the Section, Dr. A. W. Brayton of Indianapolis, has received the following titles of papers.

Treatment of Pigmentary Diseases of the Skin, by Dr. John V. Shoemaker, Philadelphia, the Chairman of the Section on Materia Medica and Therapeutics. Dr. Shoemaker will also hold a clinic on some cases of cutaneous diseases which will be collected by Dr. J. M. Blaine of Denver, the local Chairman of the Section.

The Causes of Syphilis, by Alfred E. Regensburger, San Francisco; Two Cases of Marked Iodin Intoxication with Treatment, by A. H. Ohmann-Dumesnil, St. Louis.

Dr. Wm. S. Gottheil, New York, will read two papers illustrated by casts and photographs.

The Causes of Baldness, by J. M. Blaine, Denver.

Leukemia Cutis, by Wm. Gilbert Hay, San Francisco.

Tuberculosis of the Skin, by A. W. Brayton, Indianapolis.

Syphilis and its Relation to Consumption, by Lincoln Mussey, Denver.

Dr. Wm. H. Davis of Denver, has promised a paper, and papers are expected from Drs. Wm. T. Corlett, Cleveland; T. C. Gilchrist, Johns Hopkins, Baltimore, and Robert Hessler of the Central Hospital for Insane, Indianapolis, on "The Effect of Thyroid Medication on the Diseases of the Skin," and a paper from Dr. L. D. Bulkley, New York.

Dr. Wm. T. Corlett writes the Chairman of the Section that he has visited Hot Springs and there will be several attendants on the Section with papers from that locality.

The Section will hold its session in the parlor of Unity Church in the same building with the Section on Materia Medica, and but one short block from the headquarters of the ASSOCIATION, the Brown Hotel.

All additional titles of papers should be sent at once to the Chairman of the Section or to the Secretary, Dr. T. C. Gilchrist, Baltimore, in order that they may appear on the permanent and preliminary programs and announcements.

SOCIETY NEWS.

Florida Association of Railway Surgeons.—The annual meeting of the Florida State Association of Railway Surgeons will be held at Jacksonville, Fla., Monday, April 25, 1898, at 10:30 o'clock, A.M. J. Harrison Hodges, M.D., Gainesville, Fla., President.

South Carolina Medical Association.—The forty-seventh annual meeting of the South Carolina Medical Association will be held at Harris Lithia Springs, April 13 and 14, 1898. Titles of papers should be sent to the Secretary, who also desires members expecting to attend the Denver meeting of the AMERICAN MEDICAL ASSOCIATION to advise him. E. F. Parker, M.D., Corresponding Secretary, Charleston, S. C.

Ohio State Medical Society.—At the next annual meeting of the Ohio State Medical Society, Dr. Senn will deliver the address in surgery; Dr. Hare has promised to deliver the address in medicine and a number of the ablest practitioners in Ohio have prepared papers. Matters of interest to the whole profession in the way of medical legislation, will be presented by the State Board of Registration. The headquarters for the Society will be at the Great Southern Hotel in Columbus. The date of the meeting is May 4, 5 and 6, 1898.

Kansas Medical Society.—The thirty-second annual meeting of the Kansas Medical Society will be held in Topeka, Kansas, May 4, 5 and 6, 1898. According to resolutions adopted last year, committees from the three State societies, Regulars,

Eclectics and Homeopaths met at Topeka, Sept. 28, 1897, and agreed as follows: "That each society would call its annual meeting at Topeka on the first Wednesday, Thursday and Friday of May, 1898. That the societies hold their meetings in separate halls, but that on Wednesday evening the three societies meet together. It is hoped that by this combined meeting matters pertaining to medical legislation and kindred subjects in which all are equally interested may be furthered. Those having a paper or important case to present or desiring any information, write W. F. Sawhill, Concordia, Kan., Corresponding Secretary.

Indiana State Medical Society.—The annual meeting of the Indiana State Medical Society for 1898 will be held in LaFayette, May 5 and 6. The wives of physicians who attend will be entertained by a committee of ladies. The meetings of the society will be held in the chapel of Purdue University, except the evening session, which will be held in Trinity Methodist Episcopal church. The Tippecanoe County Medical Society will tender a reception immediately after the evening session at the LaFayette Club, to the visitors and citizens of LaFayette. Free street car transportation will be provided members to and from Purdue University. The Central Passenger Association has granted the usual one and one-third fare for the round trip on the certificate plan, provided one hundred members avail themselves of the rates. Members intending to read papers (No titles will be received after April 15, 1898) will please send titles as soon as possible, endorsed by the secretary of their society. The hotel accommodations are ample. The laboratories of Purdue University will give continuous demonstrations of subjects in which every physician is interested. Geo. F. Keiper, M.D., LaFayette, Ind., is Chairman of the Program Committee.

Association of American Physicians.—Preliminary program of the thirteenth annual meeting of the Association of American Physicians, to be held in the Arlington Hotel, Washington, D. C., May 3, 4 and 5, 1898:

President's Address, F. C. Shattuck, Boston.

Discussion, Is a Uric Acid Diathesis an Important Factor in Pathology? Referee representing physiologic chemistry, V. C. Vaughan, Ann Arbor; referee representing clinical medicine, Wm. H. Draper, New York; co-referee representing clinical medicine, James Tyson, Philadelphia.

Bacillus Icteroides (Sanarelli) and *Bacillus X* (Sternberg), Geo. M. Sternberg, Washington.

Comparative Studies of Bovine Tubercle Bacilli and of Human (sputum), Theobald Smith, Boston.

Actinomycotic Forms of the *Bacillus Tuberculosis*; an Experimental Study, Simon Flexner, Baltimore.

Gastric Syphilis with the Report of a Case of Perforating Syphilitic Ulcer of the Stomach, Simon Flexner, Baltimore.

Some Observations on Cardiac Syphilis, I. Adler, New York. Danger of Error in Diagnosis between Chronic Syphilitic Fever and Tuberculosis, E. G. Janeway, New York.

Two Attacks of Temporary Hemiplegia occurring in the Same Individual as the Result of the use of Peroxid of Hydrogen in a Sacculated Empyema (Pleural), E. G. Janeway, New York.

Acute Interstitial Nephritis, Wm. T. Councilman, Boston.

Chronic Interstitial Nephritis (by title), I. N. Danforth, Chicago.

Acute Leucemia, M. H. Fussell and A. E. Taylor, Philadelphia.

Bacteriology of Cheese, V. C. Vaughan and Julian T. McClymonds, Ann Arbor.

A Chapter in Peripheral Pathology; the circulation in the feet, Morris Longstretch, Philadelphia.

A Case of Chronic Infective Endocarditis with Streptococci Found in the Blood before Death Treated by Antistreptococcus Serum and Experimental Researches upon the Effects of Injections of Antitoxins upon the Kidneys, W. H. Thomson, New York.

Nephritis of Malarial Origin, W. S. Thayer, Baltimore.

Experiments upon the Localization of Micro-organisms in the Spleen and the Importance of a Lesion of an Organ for the

Localization of Bacteria within it, S. J. Meltzer and T. M. Cheesman, New York.

Congenital Stenosis of Pylorus in Infants, S. J. Meltzer, New York.

Paralysis of the Left Recurrent Laryngeal Nerve in Mitral Stenosis, Wm. Osler, Baltimore.

Combined Symptoms of Myxedema and Exophthalmic Goiter, Wm. Osler, Baltimore.

The Renal Form of Enteric Fever, J. C. Wilson, Philadelphia. Gastric Carcinoma associated with Hyperchlorhydria, D. D. Stewart, Philadelphia.

The Diffuse Infiltrating Form of Secondary Melanosarcoma of the Liver (by title), L. Hektoen, Chicago.

A Case of Myxedema and Albumosuria; Treatment with Thyroid Extract; Death, R. H. Fitz, Boston.

Some Usually Overlooked Physical Signs in Chest Diseases, Norman Bridge, Los Angeles.

Studies of Antitoxins for Tuberculosis, E. L. Trudeau and E. R. Baldwin, Saranac Lake.

Report of a Case of Madura Foot, J. H. Wright, Boston.

Antitoxin Treatment of Pneumonia, A. H. Smith, New York.

PUBLIC HEALTH.

The Teeth and the Soil.—Examinations of recruits in Bavaria and Sweden conducted on a large scale have confirmed the assumption that the richer the soil in lime and magnesia, the harder the drinking water, the more perfect the development of the teeth.—*Munch. Med. Woch.*, No. 3, 1898.

Health in Chicago.—The report for February gives 2023 deaths during the month, a rate of 1.26 per 1000. The rate for the corresponding month in 1897 was 1.09. Of these 2023 deaths, 525 were of persons under 1 year old and 231 between 1 and 5 years. The chief causes were: Pneumonia 296, nervous diseases 243, consumption 215, bronchitis 139, heart disease 126, acute intestinal diseases 106, cancer 75, diphtheria and membranous croup 64.

Detention of an Infected Ship at Quarantine.—Health Officer, Dr. Doty, New York harbor, has detained the steamship *Strabo* from Rio Janeiro because of the death of the cook by yellow fever during the voyage northward. The captain of the vessel was ill with that disease on the trip, but he recovered and was able to resume the command of the vessel. The *Strabo* stopped at Santa Lucia and was there disinfected. She was again disinfected under the direction of Dr. Doty and then allowed to proceed.

Progress in the Production of the Diphtheria Toxin.—L. Martin reports that he has succeeded in obtaining a toxin that kills at 1 to 500, and describes the special medium best adapted for the purpose, a permanently alkaline bouillon. But besides the importance of a well adapted medium, there is also the necessity of a particularly toxigenic race of microbes. He asserts that the toxigenic function and the virulence of a microbe are quite distinct properties. This fact explains the sudden fatal syncope in certain cases of apparently mild diphtheria, as even slightly virulent microbes may be capable of secreting powerful toxins. He therefore adds that in any case in which the exudate produces cultures in twenty-four hours, resembling the diphtheria microbe in appearance and reaction to stains, the patient should be considered affected with diphtheria.—*Annales de l'Institut Pasteur*, January 25.

Prophylaxis of Diphtheria in Hospitals.—For two years Heubner has made a practice of having all the children in his pediatric clinic injected with 0.8 c.c. Behring serum, 200 units, every three weeks as a preventive against diphtheria contagion. During this period there has not been a single case of contagion except once, when to test the necessity of the measure, the injections were suspended for a while and four children were found to have contracted the disease imported by a visitor. The preventive injections were resumed and there has been no case since among the five hundred children that have been in

the hospital. The children bear these small but effective doses without disturbance of any kind, in spite of their feeble condition.—*Deu. Med. Woch.*, February 10.

Concentrated Diphtheria Antitoxin.—Bujwid announces that he has succeeded in producing an antitoxin of which 1.5 to 3 c.c. contains 1000 units. He accomplishes this by slowly freezing and then slowly thawing the antitoxin, which separates into a yellow lower and upper colorless layer. The lower layer contains almost all the immunizing properties, which are thus concentrated in it.—*Deu. Med. Woch.*, February 24, from *Przegląd Lekarski*, No. 19.

For the Prevention of Premature Burials.—In the New York legislature a bill is pending whose intent is to establish mortuaries, in all large cities, for the detention of all human bodies for a period of seventy-two hours after the supposed dying. This does not apply to cases where the cause of death is an infectious disease. In cities of the smaller size, namely those whose population is less than ten thousand, it is provided that no mortuaries shall be necessary unless the cemeteries thereat have more than one hundred burials each per annum.

Dispensary Statistics for New York.—The State Board of Charities of New York State will report to the legislature some rather startling statistics bearing on the dispensary abuses complained of by members of the medical societies, which have resulted in the introduction in the legislature of a bill to provide for the regulation of dispensaries in cities. Reports received by the board from sixty-six or more dispensaries in the borough of Manhattan for the past year indicate that not less than one-half of the people of New York city are receiving practically free medical attention. The following are the statistics for the seven largest cities in the State:

	Number of patients.	Per cent. of population.	Number of prescriptions.
New York . . .	1,077,140	71.0	1,699,468
Brooklyn . . .	252,695	31.3	455,940
Buffalo . . .	14,886	5.8	32,509
Rochester . . .	2,476	1.8	6,698
Albany . . .	20,345	21.4	17,939
Syracuse . . .	8,796	9.9	6,116
Troy . . .	715	1.2	716

Besides the medical relief furnished by dispensaries, various charitable and religious societies in the city of New York provide medical attendance for the poor at their homes, and it is a well known fact that a certain proportion of all city practitioners give gratuitous treatment to many patients without charge. It is said to be a not uncommon occurrence in New York to find families whose income ranged from \$20 to \$40 per week going to the dispensary for treatment, and in one instance a business man and real estate owner worth over \$100,000, was one of the free patients.

A Radical Improvement in Water Filtration.—The fact is demonstrated that aluminum is as excellent a purifier of water as there is. The salts of this metal are insoluble in water, and, consequently, it is plain that when these salts are formed the water can be strained and the impurities removed therefrom. Perhaps the most practicable method of purifying water by this means is the trough method, as it is called, the trough being composed of plates of aluminum and zinc or iron, six or eight inches apart. One end of the tank affords an entrance for the volume of water which passes over the top of one plate and thence under the plate next to it, this being accomplished by the fact that the elevation of the several plates is different. In connection with this tank or trough, there is an electric generator of moderate size, and, though aluminum will not form the negative pole of a current, the other plates used will. Now, as it is always the case that when an electric current comes in contact with water in this manner it decomposes a certain portion of the fluid, as it were, the result of such decomposition is that ozone is formed and oxygen freed, the meaning of this being the absolute extinction of life in any microbes or organic matter

which the water might contain, leaving it, after meeting the purification the salts of aluminum occasion, as clear and healthful as the water which flows from the purest spring.

The New York City Board of Health.—In no small measure is the administration of this Board a factor to the whole country, for that city is the gateway to commerce and immigration: it is the largest distributing point for manufactured supplies to the whole country. The appointment of Mr. Nathan Straus as President of the Health Board under the new administration gave a hope to the citizens that this important branch of the municipal government would be administered in the interests and for the protection of the people; for as has been well pointed out, he had as a private citizen done more than any other one man in the entire city to mitigate the evils generated by impure milk. He had studied certain phases of the problems of public health, and was equipped for the duties of the position as few men could be. Since he took office the Health Board has been made such a target for criticism from the Mayor's office that early in March he resigned as President of the Health Board, and within an hour the Mayor appointed Michael C. Murphy, previously a clerk in the first district court. The new appointee has been a Tammany leader of late years. Tammany discovered his versatility. He has represented his district in the Assembly and the Senate: he has been excise commissioner, and is now President of the Health Board. This appointment is generally regarded as unfortunate from a sanitary standpoint, and calls to mind a recent expression by the editor of *Public Health*, when speaking on the water scandals of Philadelphia, this event "*shows the utter helplessness of the people in the presence of political adventurers.*" The present administration is carrying its economies to the danger point in this department, especially in that line of retrenchment that has abolished its mercantile inspection service. It may be added that Mr. Straus was desirous of devoting his salary as president, and as much more as shall be needed, to erect a milk-sterilizing plant for the infants at the Randall's Island asylum, where the death rate has always been very high. An important legislative measure, affecting the future death rate of New York City, is the proposed establishment of a State sanitarium in the Adirondack Mountains for the treatment of pulmonary tuberculosis. The death rate from this scourge is very high throughout the entire country. In the State of New York alone, statistics show that thirteen thousand deaths occur annually as the result of this disease. The city of New York appropriated the sum of \$60,000, for the Board of Health of the city, to be used in removing deserving persons suffering from tuberculosis from tenement houses and sending them to special institutions. A home for consumptives exists in Brooklyn; one has been recently established within the upper wards of New York. These are steps in the right direction, but science has proved that climatic conditions form as large a factor in the development of this disease as in its cure. New York State is fortunate in having within its bounds a region offering the right climatic conditions for the retarding and often for the cure of this disease. The suffering in the city, especially in the tenement house districts, is extreme, and to the ignorance of their denizens is largely due the spread of this disease. Nothing but the removal of a patient from a home will protect the inmates of that home from the danger of contagion. Public sentiment in this State must be aroused to the point of demanding that right provision shall be made for the care and possible cure of those suffering from consumption. Private enterprise has done much, but it can not do what the State can and should do. New York is fortunate in having had an experiment station under the best scientific control, which offers a precedent and is a proof of what may be done. Dr. Trudeau, who helped to establish and who now controls the sanitarium at Saranac, N. Y., has demonstrated the possibilities of caring for many of those persons who suffer and die because the State has not awakened to its duties in that direction.

BOOK NOTICES.

Record of the Class of '98, Keokuk Medical College. Cloth. Illustrated. Keokuk, Iowa, 1898.

This college annual contains illustrations of the college buildings, clinics, several classes and members of the faculty, with other matter usually found in college annuals. The volume is a credit to its publishers, the class of '98.

The Retrospect of Medicine. Edited by James Braithwaite, M.D., London, and E. F. Trevelyan, M.D. London, B.Sc., M.R.C.P. Vol. 116. July-December, 1897. London: Simpkin, Marshall, Hamilton, Kent & Co. Ltd., 1898.

This half-yearly journal contains "a retrospective view of every discovery and practical improvement in the medical sciences." The first 128 pages are devoted to abstracts of the "most practical articles in the volume." The remainder presents citations from diverse journals concerning practical medicine, surgery and obstetrics and gynecology, comprising 110 citations.

Transactions of the Ohio State Medical Society. Edited by R. Harvey Reed, M.D., Columbus, Ohio. Cloth. Pp. 488. 1897.

This volume contains the proceedings of the fifty-second annual meeting, held at Cleveland, Ohio, May 19, 20 and 21, 1897. There are five addresses, nine papers on surgical subjects, six on medical, five on mental and nervous diseases, with a number on gynecology and obstetrics, ophthalmology, rhinology and laryngology, dermatology, and forensic medicine. The minutes, constitution and by-laws, obituaries and reports comprise the remainder of the volume. A number of inserted tables add to the value of the papers. The book is on good paper, well edited, and a decided credit to the society.

Transactions of the Royal Academy of Medicine in Ireland. Vol. xiv. Edited by William Thomson, M.A., F.R.C.S., General Secretary. Surgeon to the Richmond Hospital, Dublin. Cloth. Pp. 420. Illustrated. Dublin: Fannin & Co., Ltd., Grafton St. London: Bailliere, Tindall & Cox. 1896.

Besides the lists of officers, fellows, members, student associates, and the rules, annual report and treasurer's report, this volume contains fifty papers read before the sections of medicine, surgery, obstetrics, pathology, state medicine, and anatomy and physiology. The illustrations and tables are gotten up in good style, the full page plates being especially noticeable additions.

Report of the Health Officer of the District of Columbia. 1897. Cloth. Pp. 339. Maps. Washington: Government Printing Office. 1897.

This volume contains the usual data found in reports of this nature and includes much valuable reference matter for the physician or student carrying out the investigations on sanitary and vital statistic lines. The book is well indexed and also contains an index to the laws and regulations relating to the public health. The maps are specially valuable additions to the book.

NECROLOGY.

WILLIAM E. CLARK, M.D., River Forest, Ill., died March 22, the result of a surgical operation. Dr. Clark was born at Lebanon, Conn., Feb. 22, 1819, of illustrious Puritan stock, was a graduate of Vermont Medical College, and practiced medicine at Rochester, N. Y., and Coldwater, Mich., before settling in Chicago in 1852. He entered the army in 1861 as surgeon of the Fourth Michigan Infantry, and in 1863 was given charge of the Washington Hospital, where he remained until the close of the war. He returned to Chicago in 1866 and practiced here until his illness of two weeks ago. Dr. Clark was a brother of Grace Greenwood, the Washington authoress, and of Major Charles E. Clark, a prominent retired army officer of Washington.

ELIZABETH S. DALBY-NORRED, M.D., born in Wells County, Ind., Oct. 14, 1843, died at her home in Minneapolis, Minn., March 21. She was married to Dr. Charles H. Norred in 1865 and in 1881 was graduated from the Woman's Medical College of Chicago. Her connection with various hospitals and activity in church work, added to her membership in the AMERICAN MEDICAL ASSOCIATION and several other medical organizations, contributed much to her reputation. The interment was at Elkhart, Ill.

LEWIS REED, M.D., born in Bridgeton, N. J., in 1806, died at Ocean Grove, N. J., March 22. After practicing in Millville, N. J., where he remained until 1856, he became the first mayor of Atlantic City, holding the office for four terms. He was afterward appointed postmaster of that city by President Lincoln and served through two administrations with signal ability. Seven children are his survivors, five of whom are sons, Dr. Thomas K. Reed of Atlantic City being one.

JOHN DWYER, M.D., New York University Medical College, 1871, of Hartford, Conn., died from rheumatism, March 20. He was unmarried, a native of Ireland, and, as far as known, without near relatives in this country. As a man and a physician he was highly esteemed.

HENRY BEDELL CRANE, M.D., University of Pennsylvania, 1883, died at his home in Newark, N. Y., March 23, aged 42 years. A widow and four children survive him.

JOHN B. BROOKS, M.D., Reading, Pa., March 19, aged 65 years.—Joseph D. Couch, M.D., Cambridge, Mass., March 16.—C. L. Cudlipp, M.D., Richmond, Va., March 14, aged 33 years.—E. Dawley, M.D., Anamosa, Iowa, March 20, aged 50 years.—Joel Heldmann, M.D., Baltimore, March 23, aged 78 years.—S. G. Pickett, M.D., Elgin, Ill., March 21.—William H. Smith, M.D., Intercourse, Pa., March 16, aged 41 years.—John Mason Strong, M.D., Charlotte, N. C., March 16.—Assistant Surgeon George Clinton Hubbard, U. S. N., died in Washington, D. C., March 20; burial in Norwich, N. Y.

DEATHS ABROAD.—Dr. Mariano de la Paz Graells, one of the oldest professors in Spain and a distinguished naturalist, aged 90 years.—Dr. Oscar Hasse of Nordhausen, aged 61 years.—Dr. Didier, lecturer on physiology in the Catholic medical faculty of Lille, and vice-president of the Anatomico-Clinical Society of that town.

MISCELLANY.

University of Pennsylvania.—Certain graduates of the University of Pennsylvania of the class of 1848-49 have asked the editor to find out how many of the old class are still alive and their present address, as it is desired to have a reunion, if possible, in 1899. Any address sent to the editor of the JOURNAL will be duly forwarded. Medical exchanges please copy.

Diphtheria from Laboratory Infection.—Riesman (*Phil. Med. Jour.*, March 5) reports a case of laboratory infection, of value in determining the period of incubation of this disease, about which there still exists much obscurity and which in this case was less than forty-eight hours, probably between forty and forty-three hours. In this infection the bacteria were of the highest degree of virulence possible and were deposited in large numbers directly on the surface that became the seat of the disease.

A New Pathogenic Chromogenic Bacillus.—Gorham (*Journal of the Boston Soc. of Med. Sci.*, March) describes a new bacillus resembling the bacillus pyocyaneus. It differs from it, however, in the following points: 1. It is provided with several flagella scattered over its whole length, while the bacillus pyocyaneus has but one or rarely two at one or both poles. 2. It has never been seen to grow out into chains or filaments of more than two elements, no matter in what culture medium it is grown. 3. The culture-media never show fluorescence

as do those on which the bacillus pyocyaneus is grown. The color is always green, with no trace of yellow, and only one pigment can be isolated; from cultures of the pyocyaneus two or three pigments can be isolated. 4. Indol is produced by the bacillus pyocyaneus, while tests of this form were negative. 5. In bouillon cultures this organism produces a cloudy medium with a thick mycoderma, unlike the corresponding changes of the pyocyaneus.

Diseases of the Nerves Consecutive to Suppurating Inflammations of the Fingers.—Gerhardt reports four cases of motor, sensory and trophic disturbances in the region of the nerves of the arm, and diffuse multiple neuritis, appearing a few weeks after a paronychia, necropsy furuncle or crushed fingers. Each gradually recovered.—*Deu. Med. Woch.*, January 20.

Women Students at Berlin.—A hundred and sixty-two women are now studying at the University, although by no means admitted to the full privileges of the University; three, in the theologic course; three, law; and one, medicine. There are twenty-six Americans among them. A separate dissecting and preparation room has been set apart for women students, with a special course of lectures by Professor Benda.

New Secret Order for Physicians.—The Mystic Order of Disciples of Esculapius, is being organized by Frank C. Hoyt, M.D., superintendent of the Iowa Hospital for the Insane, Clarinda, Iowa. It is designed to work in conjunction with medical societies, and in no way supplant them, and the enterprise is fraternal, not commercial in character. Full information can be obtained by addressing Dr. Hoyt.

Amputations of Extremities without Ligatures.—Barber has used this method in six amputations (*Med. Age*, March 10), all acute, all of lower extremities, and all the result of crushing injuries. He asserts that the advantages are that no blood is lost, there is no oozing, and no time is lost in clamping, tying and applying hot cloths to arrest hemorrhage. He uses the ordinary rubber roller bandage and a section of rubber tubing wound tightly around the limb above this bandage before it is removed. After the amputation is made and the flaps nicely adjusted, he takes a long piece of catgut and with a good sized needle stitches into the muscles, next the bone, at one edge of the wound, and sews back and forth the same as in closing any wound by deeply buried sutures. Bringing the muscular tissue into snug apposition, not too tightly, he whips the outer and last row of stitches by the over-and-over method and then stitches the skin over all. The Esmarch is then removed.

Massage as an Occupation for the Blind.—Bennett (*Phil. Med. Jour.*, March 5) advocates this for the large number of blind in this country, which he estimates at 56,000 persons, the majority of whom are dependent on private benevolence or public funds. He addressed inquiries to every superintendent of a State school for the blind throughout the country and from their responses believes that the percentage of their pupils who become self-supporting after graduating are: Illinois, 6 per cent. of the males and 1.5 per cent. of the females; North Carolina, 80 per cent. of the male whites; Texas, 75 per cent. of the males; Wisconsin, 20 per cent. of the males and 5 per cent. of the females. He considers the mechanical trades barred to the women while in case of the men there exists a prejudice against employing the blind. The women's chances in the matrimonial market he considers *nil*. He says the blind can make massage their own particular occupation, and they possess some qualifications that eminently fit them to excel in this; among these qualifications delicacy of touch and the blindness itself.

Chronic Purulent Otitis Media.—Burnett (*Phil. Med. Jour.*, February 26) reports four recent cases of excision of the malleus and incus for this condition. The results were an immediate lessening of the discharge in all the cases, total cessation and

cicatization of the fundus in two, and improved hearing in three. He finds two years may be necessary for total cessation of discharge after excision. As a rule, the longer the duration of the purulency, the longer the after-treatment necessary before a cure of the chronic purulency is affected. While an improved state of the discharging ear can be promised immediately, from an operation, the time of total cessation of the discharge can not be accurately foretold. This operation of excision, with the better drainage it affords, and the more complete antisepsis permitted, the general health of the patient being improved, the hearing often benefited and the advance of caries and necrosis checked, he considers an efficient prophylaxis against deafness and serious intracranial lesions.

Recurrent Multiple Neuritis of Specific Origin.—In "Some Rare Affections," in the *New York Polyclinic* for February 15, is reported a case of this rare condition in a man 35 years old. There was marked paresis of both lower extremities, considerable atrophy of the anterior thigh muscles, weakness of these and the lower spinal muscles. The muscles below the knees were less affected, but distinct atrophy of both anterior tibial groups. The anterior thigh muscles did not respond to the faradic current and galvanic response was diminished. The knee jerks were absent. On mercurial treatment the right knee jerk soon returned, the left only by reinforcement. The volume of the thigh muscles of the right thigh improved more rapidly than of the left. In eight weeks the patient was able to walk without assistance, but there has been vacillating behavior of the knee jerks, immobility of the pupils, transitory ptosis and transitory palsy of the tongue during the succeeding two years, with subjective disturbances of sensation at intervals.

Control of Nasal Hemorrhage.—Gleason (*Laryngoscope*, March) reports having for a year used the following method in severe post-operative nasal hemorrhage: Wrapping a piece of cotton loosely about a probe he thrusts it, dripping with a fifteen volume solution of hydrogen peroxid, along the floor of the nose until the pharynx is touched. The mass of cotton should be large enough to completely fill the inferior meatus. It is necessary, in most cases, to hold the cotton in position for a few moments with the finger tip, during which time the probe is withdrawn. If necessary, the plug of cotton is then held in position by means of smaller pieces of absorbent cotton, saturated with peroxid, packed into the anterior naris in front of it. After the smaller masses of cotton are removed from the anterior portion of the naris, there yet remains a large plug of cotton, which, if removed quickly, suddenly removes pressure from the bleeding spot and causes renewed hemorrhage. This accident can often be prevented by removing the mass of cotton very slowly, with steady, gentle traction exerted at intervals of two or three minutes in order that five or ten minutes elapse before the plug is entirely withdrawn from the nose. In cases of severe nasal hemorrhage, it is well to allow at least twenty-four hours to elapse before removing the packing, and if hemorrhage then recurs to attempt to control it by the insertion of a smaller mass of cotton dripping with peroxid.

Myxedema—like Conditions in the Negro.—Berkley (*Am. Jour. of Insanity*, January) reports the results of an investigation carried out in 1897 on about 1600 inmates of the city asylum and the adjacent almshouse in Baltimore. Of the 1600 inmates, about 300 were negroes. Eight cases of a peculiar thickening of the skin, local in character, in the blacks, was noted, identical in all respects with that present in cases of sporadic cretinism in the Caucasian race, but less diffuse. Among the idiots four examples were noted, one in a case of parietic dementia in the third stage, one in a case of acute mania, one in a demented patient whose history was unobtainable, and one in an individual who exhibited no mental change beyond extreme slowness. Departures from the normal in the thyroid were always pres-

ent, in seven cases being non-palpable or below normal size and in one case enlarged. In two cases the hair was coarse, thin and rough. Abnormally broad bones existed in but one case, the idiot approaching a cretinoid state, but even in this case there seemed no defect in the growth lengthwise. The regions of the fontanelles had no abnormalities, though the skull development showed many abnormalities. The secretions of the skin seemed normal, with little dryness and roughness over the myxedematous areas. But two cases showed changes in the general bulk of the body, and one case pendulous abdomen. Trophic lesions and enlargement of the lymphatics was not found.

Pregnancy and Ovarian Tumors.—Swan (*Bull. of the Johns Hopkins Hosp.*, March) reports another case of solid ovarian tumor complicating pregnancy, and from a review of the literature on the influence of pregnancy on the growth of such tumors, draws the following conclusions: 1. Solid neoplasms of the ovary complicating pregnancy are exceedingly rare. 2. The diagnosis may be difficult. In certain cases it may be aided by recto-abdominal palpation under narcosis, using Kelly's method to gently produce artificial descensus of the uterus. The physical examination with the signs of pregnancy, and those which belong more particularly to solid ovarian growths, generally enable us to make a probable diagnosis and one sufficient to warrant an exploratory section. 3. The prognosis in case of solid growths of the ovary complicating pregnancy is much worse, both for the mother and child, than in those of cystic neoplasms of these organs. Abdominal section and extirpation of solid tumors during the early months of pregnancy produce equally good results, so far as the fetus is concerned, as in case of cysts. The result to the mother depends on the malignant or benignant nature of the growth. 4. In extirpation during the second to fourth month of gestation, the maternal mortality is but 5 per cent., due to hemorrhage, shock, sepsis, etc., whereas the fetal mortality due to abortion is only 20 to 22 per cent. as compared with 40 per cent. for the former, and 80 per cent. for the latter when these cases are left to unaided nature. 5. The compulsory operation (during the latter half of gestation, during labor, or the puerperium) will rarely be required.

Medical Board Can Appeal.—The Oregon statute of 1895, authorizing the organization of a board of medical examiners, empowers it, among other things, to revoke the license of practicing physicians for unprofessional or dishonorable conduct. In case of a revocation, the licentiate is given the right of appeal to the circuit court in and for the county in which the hearing was had. Either party may appeal from the judgment of the circuit court to the supreme court in like manner as in civil actions, within sixty days after the rendition thereof. Now how about an appeal by the board of medical examiners? The case of *State vs. Estes* developed the contention that the board of examiners not being a party to the action, as such had no authority to take an appeal from a judgment of the circuit court overruling the action of the board in revoking the license of the defendant. Even the supreme court of Oregon admits, in the decision on the point which it rendered Dec. 7, 1897, that it is difficult to determine from this crude piece of legislation just what procedure is meant to be established for taking and perfecting an appeal from the circuit to the supreme court when the judgment is in favor of the accused practitioner. The language of the act, that "either party may appeal," it says, would seem to allude more especially to the parties to the proceeding and not to the tribunal charged with the function of determining the cause as between them. But there is a further provision in the statute that is a plain recognition of the right, while not conferred in express terms, of the board also to appeal from the decision of the circuit to the supreme court in case the judgment should be adverse to its

decision, and the supreme court thinks its effect is to empower the board to prosecute an appeal in vindication of its own findings, and it accordingly holds that the board may appeal in such case. Attorneys, the supreme court further holds, are sufficiently authorized to prosecute an appeal for the board when they have been directed to do so by its president, and the board has afterward ratified and confirmed their action in the matter.

Antitoxin Manufacture by Cities.—Dr. B. T. Whitmore of New York is out in a trenchant article against the manufacture of antitoxin by the municipality of New York city. This paragraph presents the fact and the essence of the argument: "The City of New York is engaged in the drug business at the expense—and it is a heavy expense, too—of the people, and in defiance of the principle and fact that it is no part of the business of government to engage in or be identified in any way with artistic, commercial or industrial pursuits. Attention has been called several times to this petty and pitiable attempt to fasten paternalism upon the administration of municipal affairs. But never yet have I seen the point made that New York City's identification with the drug business, in manufacturing and selling antitoxin, is maintained at a cost which is an absolute and foolish waste of public money. This is the truth, however, and it will take but a few moments and a few figures to estimate it." Dr. Whitmore then proceeds to show that "the city is paying \$60,000 every year for \$10,000 worth of antitoxin," from which it is clear that the New York taxpayer "is paying pretty dear for his therapeutic whistle." "Is there any reason in the world," the article continues, "why with these overwhelming facts against it, the city of New York should continue in the manufacture of antitoxin? None. A State law provides for the inspection of all antidiphtheritic serum by a board of examiners before its exposure for sale. It can not be urged, therefore, that the city is in the business for the protection of the public, for the board of examiners would offer that protection amply. It has not, therefore, a leg of any kind to stand upon." When the New York city enterprise was started there was no available supplies of reliable antitoxin and there was reason therefore for the city undertaking the manufacture of the article. Under present conditions, however, those municipalities which, like New York, entered the field in an emergency, can now well afford to withdraw in favor of private enterprise, providing such compensating legislation is passed as will insure pure and adequate supplies of antitoxin on equitable terms to the public. —*Western Druggist*, March.

Hypertrophy of the Prostate.—In the *Medical Record* for March 5, Meyer writes on the Bottini galvano-caustic operation for hypertrophy of the prostate. After the bladder has been carefully irrigated and emptied, the posterior urethra is locally anesthetized with cocain or eucain, $1\frac{1}{2}$ drams of a 1 or 2 per cent. solution (eucain 5 per cent.) being injected. The incisor introduced, Bottini burns with his incisor one, two, or, better still, three grooves at one sitting; a short one toward the symphysis, another just opposite directly backward toward the rectum, and a third one through that lateral lobe of the prostate which appears to be the larger one. According to the number of grooves cut, the operation requires from two to five minutes. Soon after the operation most of the patients complain of a burning sensation when commencing to pass water. They may get up right after the operation in order to urinate, and can be permitted to be permanently out of bed on the second day, the general reaction of the operation being in most instances almost *nil*. If the bladder has been carefully irrigated, the patients will rarely develop any rise of temperature; bleeding, if there be any at all, is generally of minimal amount. The urine passed during the first night following the operation is often macro-

scopically free from blood. In more than eighty cases of this kind, Bottini has not seen a single serious hemorrhage. For this reason he warns against the use of a permanent catheter. Thus the after-treatment is comparatively very simple. If necessary, the bladder should be washed out daily in order to improve the present cystitis, best with a cold solution, as this will strengthen the contractibility of the detrusor muscles. Bottini's operation leaves the important anatomic parts absolutely intact, without destroying tissues which for certain periods of the life of the male subject are of great importance (vasa deferentia, testicles), and without sharing, to a great extent at least, the dangers of other radical operations (ligation of internal iliacs, total extirpation).

Book Announcements.—Messrs. Lea Brothers & Co. announce for early publication the following books by eminent authorities:

A MANUAL OF OTOTOLOGY. By Gorham Bacon, A.M., M.D., professor of otology in University Medical College, New York. With an introductory chapter by Clarence J. Blake, M.D., professor of otology in the Harvard Medical School, Boston, Mass. In one 12mo volume, with numerous illustrations.

THE TREATMENT OF SURGICAL PATIENTS BEFORE AND AFTER OPERATION. By Samuel M. Brickner, M.D., visiting surgeon at the Mt. Sinai Hospital, New York. In one volume of about 400 pages, with illustrations.

A TEXT-BOOK OF DENTAL PATHOLOGY, THERAPEUTICS AND PHARMACOLOGY. Being a Treatise on the Principles and Practice of Dental Medicine. By Henry H. Burchard, M.D., D.D.S., special lecturer on dental Pathology and therapeutics at the Philadelphia Dental College, Philadelphia. In one octavo volume of about 550 pages, with 400 illustrations.

THE PRINCIPLES OF TREATMENT. By J. Mitchell Bruce, M.D., F.R.C.P., physician and lecturer on materia medica and therapeutics at Charing-Croes Hospital, London. In one octavo volume.

DISEASES OF THE NOSE, THROAT, NASO-PHARYNX AND TRACHEA. A Manual for Students and Practitioners. By Cornelius G. Coakley, M.D., professor of laryngology in University Medical College, New York. In one volume, 12mo, of about 400 pages, with numerous illustrations, many of which are in colors.

DISEASES OF WOMEN. A Manual of Non-surgical Gynecology, designed especially for the use of Students and General Practitioners. By Francis H. Davenport, M.D., instructor in gynecology in the Medical Department of Harvard University, Boston. Third edition, thoroughly revised and enlarged, with many additional illustrations.

A TREATISE ON GYNECOLOGY. By E. C. Dudley, A.M., M.D., professor of gynecology in the Chicago Medical College, Chicago. In one octavo volume of about 600 pages, with 425 illustrations, many of which are in colors.

A TEXT-BOOK OF ANATOMY. By American Authors. Edited by Frederic Henry Gerrish, M.D., professor of anatomy in the Medical School of Maine. In one imperial octavo volume, copiously illustrated in colors.

MANUAL OF SKIN DISEASES. With Special Reference to Diagnosis and Treatment. For the use of students and general practitioners. By W. A. Hardaway, M.D., professor of skin diseases in the Missouri Medical College. Second edition, entirely rewritten and much enlarged. In one 12mo volume with illustrations.

THE PRINCIPLES AND PRACTICE OF OBSTETRICS. By American Authors. Edited by Charles Jewett, M.D., professor of obstetrics in the Long Island College Hospital, Brooklyn, N. Y. In one octavo volume, with many illustrations in black and in colors.

MESSRS. P. BLAKISTON, SON & Co., have in press the third edition of "Hamilton on Tumors," rewritten and enlarged; copious illustrations.

Against the Caffery Bill.

ROOMS OF THE NEW YORK
BOARD OF TRADE AND TRANSPORTATION, {
203 BROADWAY.
NEW YORK, March 26, 1898.

HON. JACOB H. GALLINGER,

United States Senate, Washington, D. C.

Dear Sir:—The threatened invasion of this country by cholera in 1892 was the occasion for the appointment by the New York Board of Trade and Transportation of a special committee which investigated with great thoroughness the question of health protection by quarantine in the United States, and the Board cast its influence for the bill which became a law on Feb. 15, 1893, viz.: "An act granting additional quarantine

powers and imposing additional duties upon the Marine-Hospital Service."

The epidemic of yellow fever last year in the Southern States, with the attendant loss of life and disturbance of commerce and travel, and the lack of harmony of action between the State, or local and the National Health Authorities, and the inability of the latter to enforce its regulations seemed to call for further legislation.

This Board, therefore, on Nov. 10, 1897, appointed a second able special committee to investigate the existing conditions, and that committee after four months of careful study and inquiry reported its conclusions on March 9, 1898.

The Committee addressed personal letters of inquiry to nearly one thousand professional men, sanitarians and men engaged in transportation and commercial pursuits.

The inquiries were directed mainly to the following points, viz.:

FIRST.—Quarantine status and administration in foreign countries furnishing precedents for the United States. A, Border; B, Internal.

SECOND.—The present status of quarantine in the United States. A, Border Defense; B, Interstate; C, State and Local.

THIRD.—The existing system of quarantine administration in the United States. A, Cost; B, Injury to and Restrictions Imposed on Commerce and Travel; C, Security afforded.

FOURTH.—Legislation needed for lessening injury to and restrictions on commerce and travel, and to afford greater security to the country. A, Increase Power of Marine-Hospital Service and How; or, B, Create a National Department of Health; or, C, Create a National Department of Commerce with a Bureau of Health; or, D, other suggestions.

FIFTH.—The power of Congress under the Constitution to regulate matters affecting the health of the people. A, National; B, Interstate; C, State and Local.

Hundreds of valuable replies were received to these inquiries and only thirteen of them endorsed the proposition to enlarge the powers of the Marine-Hospital Service. All of these thirteen letters contained the one chief argument that the Marine-Hospital Service was a good nucleus to build a National Health Bureau upon.

On the other hand a very large majority of the replies expressed the opinion that the National Government can never hope to create a successful national health organization based upon the Marine-Hospital Service, as a nucleus, because in many States the bitter hostility to the Marine-Hospital Service, engendered by its own acts, is so formidable as to preclude any possibility of harmony between it and such State and local authorities. The opinion was that to give the Marine-Hospital Service still more arbitrary powers, as proposed in the Caffery bill, without the obligation to consult or in any way regard the local authorities, would only widen the breach, intensify the bitterness and render resort to force necessary to carry out the Marine-Hospital Service regulations.

An officer of the Marine-Hospital Service, in his statement to our committee, admitted that under the conditions existing in the South last Fall, the Marine-Hospital Service would have been powerless to enforce its regulations "even if it had the entire standing army of the United States at its command." For this reason few attempts were made to enforce the law locally and none met with success except where State and local authorities co-operated.

The Caffery Bill if passed would be absolutely inoperative unless backed and enforced by United States Marshals or United States troops.

It does not seem possible that Congress contemplates carrying a war of conquest into any of the States of this Union, and it would be the height of folly to enact any health law which would be a dead letter unless enforced by armed officers or troops, and when there is no intention of so enforcing it.

The consensus of testimony before our committee was overwhelmingly in opposition to the letter and spirit of the Caffery bill. It stamped the bill as narrow and wholly inadequate to meet the very pressing needs of the country. The Caffery bill exaggerates the importance of quarantine, and makes no other provision for public health protection, while advanced sanitary science pronounces quarantine to be barbarous and obsolete. The practically uniform opinion was that the country is now ready for a law which will make quarantine of constantly decreasing importance as local sanitary administration shall be stimulated and perfected. And it was very clearly shown that any law that will successfully meet the situation and the needs of the country must of necessity have due regard for the wishes and views of the people, must foster and encourage good will, a spirit of harmony and co-operation between States and between the National authorities and local authorities for

the common well being. The Caffery bill is the antipode of this view. It is abnoxious in its spirit, and would be more so in its enforcement, to the great mass of the American people in all the States.

The Spooner bill, on the other hand, is in full accord with the most enlightened modern views of health protection. It does not abolish quarantine, but in time would bring about conditions which would make quarantine almost unnecessary.

It recognizes several departments of the National Government, and every State and Territory as interested and important factors in the scheme of health protection, and gives to each a voice in the framing of health regulations, and this is done by means of organization so simple as to be immediately moved to action in emergencies. It removes friction and hostility and promotes harmony and co-operation, which are essential to the success of any National health law. It violates no principle of National or local policy.

Our Committee went over all this ground with the greatest deliberation, and although their views upon taking up the question had a decided leaning toward the proposition to give the Marine-Hospital Service the absolute and arbitrary power it asks for, they finally and unanimously reached the opinion that the passage of the Caffery bill would be a serious injury to the people of the United States by delaying and hindering the broader, better, and more certain solution of the problem which the Spooner bill will afford.

Our Committee therefore reported favorably on the Spooner bill recommending some amendments which the Board endorsed most heartily, and, as we are informed, Senator Spooner and the friends of his bill have accepted and incorporated in it.

Our Committee knowing of the great interest you take in this question, and the value which everywhere attaches to your opinions regarding it, have desired me to hand you a copy of their report, which I have the honor to enclose herewith, and to ask for it your careful consideration. They requested me at the same time to make the foregoing statement regarding their investigations and some of the considerations which influenced their conclusions.

I can only add that when I served with you in the House I had the highest regard for the Marine-Hospital Service and still have the greatest respect for it, but conditions have changed and demand a broader and more comprehensive plan of health protection, and I therefore feel that the conclusions of our Committee are wise, practical and patriotic, and I sincerely hope that they will have some influence upon Congress.

I remain very respectfully,

DARWIN R. JAMES, *President*.

Colleges.

ENSWORTH MEDICAL COLLEGE, St. Joseph, Mo., at the twenty-first annual commencement, March 8, graduated twelve new doctors.—The St. Louis College of Physicians and Surgeons awarded 105 degrees March 16.—The graduates from Keokuk (Iowa) Medical College, at the annual commencement March 15, numbered eighty.—The Kansas Medical College, Topeka, conferred eighteen degrees at the annual commencement, March 22.—The eighteenth annual commencement of the University Medical College, Kansas City, Mo., was held March 23; the graduating class numbered sixty-nine.—At the Kansas City Medical College's twenty-ninth annual commencement, March 21, forty-one degrees were conferred.

Hospitals.

THE CHICAGO HOME FOR INCURABLES has received \$40,000 from D. B. Shipman, making the erection of an annex increasing the capacity of the institution from 140 patients to 200, possible.—Emergency Hospital, Leavenworth, Kan., was burned recently; loss \$8,000.—The Atlanta (Ga.) Hebrew Orphans' Home has received £1500 from the Baroness de Hirsch. The money will be devoted to establishing a hospital in connection with the orphanage.

Louisville.

PHARMACY. Eleven graduates received diplomas at the annual commencement of the Louisville College of Pharmacy the 27th ult.

QUARTERLY.—With the April issue *Matheu's Quarterly Journal of Rectal and Gastro-Intestinal Diseases* will cease to be issued quarterly, but will appear as a monthly. At a recent meeting of the Louisville Surgical Society it was adopted as the official organ of that Society, its proceedings appearing in it exclusively. It will be changed in name to the *Louisville Journal of Surgery and Medicine*, taking in all branches of medicine and surgery losing its distinctive characteristics as a

special journal, though it is the purpose of the editor, Dr. J. M. Mathews, to include in it this department, as a special feature. Dr. Henry E. Tuley, who has been associated with Dr. Mathews in the *Quarterly*, will not be connected with the monthly.

TRUSTEES.—At the last meeting of the general council the following were elected as members of the Board of Trustees of the Medical Department of the University of Louisville: Drs. George W. Griffith and John Buschemeyer. The term of the incumbent is for ten years, service being without compensation. Dr. Griffith succeeds himself and Dr. Buschemeyer succeeds James A. Leech.

GRADUATES.—The Louisville Medical College held its twenty-ninth annual commencement on the afternoon of the 25th ult. Seventy-four graduates received diplomas.

LICENSE.—The ordinance creating a license of \$10 yearly on physicians, dentists, midwives and chiroprodists has been approved by the mayor and will at once become a law. The physicians unanimously protested against it by a petition, but to no avail.

Cincinnati.

A BILL has been introduced in the legislature to compel druggists to label all drugs or compounds sold as "poison," which contain poisonous ingredients. This does not apply to physicians' prescriptions.

A BILL has been introduced in the senate to abolish the present State Board of Medical Examination and Registration, and a new one is proposed with the reduction in the salaries of the secretary and members.

THE mortality report for the week shows: still-births, 8; zymotic diseases, 11; phthisis pulmonalis, 11; other constitutional, 7; local, 67; developmental, 7; violence, 4; total, all causes, 107; under one year of age, 20; between one and five years, 17; annual rate per thousand, 13.73; preceding week, 127; corresponding week, 1897, 110; 1896, 123; 1895, 134.

THE annual appropriations for Ohio State medical institutions is announced as follows: Athen's State Hospital, \$137,450; Cleveland Hospital, \$148,600; Columbus Hospital, \$161,125; Dayton Hospital, \$117,000; Longview Hospital, \$123,000; Massillon Hospital, \$150,000; Toledo Hospital, \$161,050; Epileptic Hospital, \$152,958.

THE senate last week passed a bill to reorganize the State Board of Health by giving it power to assume charge of affairs in localities where contagious or infectious diseases make their appearance and the local board fails to exercise proper precautions against an epidemic, by the establishment of a State bacteriologic laboratory where specimens are to be examined free, upon request, and by a new system of making uniform reports of vital statistics to the various probate judges.

Philadelphia.

PRESENT STATUS OF TYPHOID IN PHILADELPHIA.—The report of the Board of Health of this city for the week ending March 19, shows a rapid decline of the typhoid fever epidemic. It will be remembered that this epidemic started soon after the bursting of a sewer pipe, November 16, which contaminated the Wissahickon Creek and was pumped into the Queen Lane Reservoir. Although the leakage was stopped within fifteen minutes, yet the damage had been done and the outbreak of typhoid occurred until it had reached serious proportions, there being 212 cases in the city the week ending January 22, and 201 cases January 15. The week ending March 19 there were reported 57 new cases with 12 deaths, as against 81 cases and 7 deaths for the week preceding. The total number of deaths for this week were 484, an increase of 21 over last week and a decrease of 59 over the corresponding period last year. Of this number 175 were children under 5 years of age.

THE KLEBS-LOEFFLER BACILLUS AND QUARANTINE IN CITIES.—Gin Sing, a Chinaman, and his son 7 years old, are two citizens of Philadelphia. About three or four weeks ago the lat-

ter suffered from a sore throat but did not seem to be very sick. Cultures from swabs of the throat, made by the city bacteriological department, however, revealed Klebs-Löffler bacilli. It was demonstrated that the father's throat also showed the presence of this organism, although neither have ever experienced any serious inconvenience from the disease. Gin Sing is now up in arms against the city authorities for having quarantined his laundry although he is not sick enough to go to bed. Dr. J. Howard Taylor, medical inspector of the Board of Health, stated recently that science had so far failed to make any absolute diagnostic differences between the Klebs-Löffler bacillus from certain other bacilli in throat, and that to be sure that no cases of diphtheria should go unquarantined that all cultures showing the former germs would be classed as diphtheria and a quarantine instituted for the proper period, the justice of which can be at once understood.

PHILADELPHIA PHYSICIANS READY FOR WAR.—The Philadelphia Emergency Corps recently adopted the following resolution, subsequently sanctioned by the Mayor:

WHEREAS, The Philadelphia Emergency Corps has always in the past been ready to meet any and all calls to duty in the interest of the public and humanity, be it therefore

Resolved, That its members, an organized body of physicians and surgeons, hereby tender their services to the National Government should the necessity arise for the same.

Signed: Thomas H. Andrews, Medical Director; G. R. Hulsizer, Commander; William H. Ziegler, Herman Bergin, George Sinnamon, Walter Strong and R. B. Judge, Committee.

PHILADELPHIA ALSO AFFLICTED WITH GRIPPE.—La grippe, which has been quite extensive here for the past several weeks, has begun to decline. It became more common toward the latter part of February, owing possibly to sudden changes in the weather. Taken as a whole, it may be said that of those affected the cases were accompanied by excessive coughing and as a rule confined to the respiratory passages. Neuralgic symptoms were common, and extreme prostration accompanied by great chilliness of the body with flashes of heat and cold. Many cases had previously suffered with the disease, which shows the nature of this terrible malady.

Societies.

The following meetings are noted:

Illinois—Champaign County Medical Society, Champaign, March 16; Chicago Academy of Medicine, March 18; Chicago Medical Society, March 30; Peoria City Medical Society, March 22.

Indiana—Montgomery County Medical Society, Crawfordsville, March 15; Vanderburg Medical Society, Evansville, March 15; Vigo County Medical Society, Terre Haute, March 17.

Iowa—Scott County Medical Society, Davenport, March 17.

Maryland—Baltimore County Medical Association, Baltimore, March 17.

Missouri—Marion County Medical Society, Palmyra, March 17; St. Louis Medical Society of Missouri, March 19 and 26.

New York—Syracuse Academy of Medicine, March 22.

Ohio—Erie County Medical Society, Sloane, March 17; Lucas County Medical Society, Toledo, March 18.

Pennsylvania—Gloucester County Medical Society, Woodbury, March 17.

CHANGE OF ADDRESS.

Allen, G. V., from Topeka, Kas., to Murray, Neb.
Birkhofer, W. J., from Thor to Dickens, Iowa.
Booker, F. E., from 511½ N. 6th to 308 N. 12th St., Richmond, Va.
Brown, A. P., from St. Louis, Mo., to Elberfeld, Ind.
Brashear, B. B., from 211 Prospect St. to "The Clarendon," Cleveland, Ohio.
Burkhart, J. R., from Keokuk to Fort Madison, Iowa.
Best, W. W., from Louisville, Ky., to Bolckow, Mo.
Cryer, M. H., from 1527 Arch to 1420 Chestnut St., Philadelphia, Pa.
Cheadle, C. M., from Keokuk, Iowa, to Buda, Ill.
Corr, A. C., from Chicago to Carlinville, Ill.
Crockett, E. N., from St. Louis, Mo., to Long Creek, Ore.
Furay, C. E., from 2237 Seward to 2409 North St., Omaha, Neb.
Gibbs, M. D., from Hartford to Mendota, Mo.
Griffin, J. M., from Lathan to Rocky Mount, Mo.
Germer, H. G., from Chicago, Ill., to Canastota, N. Y.
Hargrove, P. M., from Keokuk, Iowa, to Kidder, Mo.
Haines, J. P., from 10 E. 22d St. to Madison Av. and 26th St., New York.
Jorgensen, P. P. M., from Iowa City to Zwingle, Iowa.
Kauffman, E. J., from Cincinnati, Ohio, to 14 E. 17th St., New York.
King, D. H., from Keokuk to Abington, Iowa.
Klunne, J. G., from Indianapolis to Mexico, Ind.
Kelsey, T. W., from Indianapolis to Converse, Ind.
Laib, F. J., from 831 Milwaukee to 711 N. Claremont Av., Chicago.

Luehr, E., from 256 92d St. to 9241 Houston Av., Chicago.
Layman, R. B., from Louisville, Ky., to Dandridge, Tenn.
Mills, W. A., from 33 W. Lexington to 302 Dolphin St., Baltimore, Md.
Nosher, M. D., from Keokuk, Iowa, to Sandwich, Ill.
McManus, E. A., from Detroit to Sherman, Mich.
Morrow, A. M., from Keokuk to Salina, Iowa.
McDougall, G. T., from 70 Farrell Av. to 588 11th St., Milwaukee, Wis.
Mott, B. I., from 705 Nicollet Av. to Sykes Blk., Minneapolis, Minn.
Nulton, Ida, from Keokuk, Iowa, to Hartford, Mo.
Patch, Wm., from Sibley to Ellsworth, Ill.
Pence, L. W., from Iowa City to Fertile, Iowa.
Parrington, J. M., from Indianapolis, Ind., to Emporia, Kas.
Robinson, J. L., from Keokuk to Monroe, Iowa.
Ryan, W. C., from Keokuk to Croton, Iowa.
Rives, W. C., from New York, N. Y., to Readville, Mass.
Smith, L. E., from 70 E. Pine to 117 W. 8th St., Chattanooga, Tenn.
Stover, E. E., from Iowa City to Lucas, Iowa.
Sugfield, H. D., from Keokuk, Iowa, to Ferris, Ill.
Spiller, O. C. H., from Indianapolis, Ind., to Maynard, Texas.
Thielen, M. H., from Iowa City, Iowa, to Chanute, Kas.
Taylor, A. A., from 915 I St., N. W., to 1103 H St., N. W., Washington, D. C.
Walker, H. T., from Keokuk to 857 Delhi St., West Dubuque, Iowa.
Wright, John, from San José, Cal., to Clinton, Ill.
Williamson, A. A., from Indianapolis to Kingman, Ind.
Woods, E. A., from 720 14th Av., S. E., to 324 15th Av., S. E., Minneapolis, Minn.

THE PUBLIC SERVICE.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from March 19 to 25, 1898.

Major Henry McElderry, Surgeon, is relieved from duty at Ft. Leavenworth, Kan., and will proceed to Omaha, Neb., and report in person to the commanding General, Dept. of the Missouri, for assignment to duty as chief surgeon of that Department.

Major George H. Torney, Surgeon, will be relieved from duty at the U. S. Military Academy, West Point, N. Y., on or about June 1, 1898, and ordered to Ft. Leavenworth, Kan., for duty.

Major John M. Banister, Surgeon, will be relieved from duty at Ft. Leavenworth, Kan., upon the arrival there of Major Torney, and ordered to the U. S. Military Academy, West Point, N. Y., for duty.

Capt. Robert J. Gibson, Asst. Surgeon, is relieved from duty at Ft. Thomas, Ky., and ordered to Ft. Meade, S. Dak., for duty.

Major Louis W. Crampton, Surgeon, will be relieved from duty at Ft. Meade, S. D., upon the arrival there of Capt. Gibson, and is ordered to Ft. McHenry, Md., to relieve Major Charles K. Winne, Surgeon.

Major Henry McElderry, Surgeon, now at Ft. Leavenworth, Kan., will proceed to Hot Springs, Ark., and report to the commanding officer of the Army and Navy general hospital for treatment therein.

Major Egon A. Koerper, Surgeon, the order assigning him to duty as chief surgeon, Dept. of the Platte, is revoked.

First Lieut. Charles Lynch, Asst. Surgeon, is relieved from duty at Ft. Sheridan, Ill., to take effect upon the completion of his examination for promotion, and ordered to Galveston, Texas, for duty.

First Lieut. John H. Stone, Asst. Surgeon, is relieved from duty at Ft. Riley, Kan., and ordered to Ft. Leavenworth, Kan.

Capt. Jefferson D. Poindexter, Asst. Surgeon, is relieved from duty at Willets Point, N. Y., and from temporary duty at Ft. Hamilton, N. Y., and ordered to report to Capt. William C. Gorgas, Asst. Surgeon, for the purpose of assisting him in examining recruits in that city, including the borough of Brooklyn.

The Journal of the American Medical Association

VOL. XXX.

CHICAGO, ILLINOIS, APRIL 9, 1898.

No. 15.

ADDRESS.

CHAIRMAN'S ADDRESS.

Delivered in the Section on Cutaneous Medicine and Surgery at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY A. RAVOGLI, M.D.
CINCINNATI, OHIO.

It is extremely grateful to me on this happy and memorable occasion of the fiftieth anniversary of this great National Association, to have the honor of welcoming you to the City of Philadelphia as Chairman of this Section. This great city where the bell rang the first time for the freedom and the independence of the United States, has been the birthplace of the AMERICAN MEDICAL ASSOCIATION, one of the largest and most powerful medical organizations in existence.

To recall to you the beginning of this ASSOCIATION, its motives and its scope would be out of place, I will therefore limit myself to a few points of history concerning our special Section.

In 1869, at the annual meeting the assembly adopted a resolution which recognized specialties as a proper and legitimate field of practice. From that time several sections of medical branches were established, no one, however, showed the necessity of a section on the diseases of the skin.

If any work on dermatologic subjects was presented previous to the publishing of the JOURNAL, I was unable to obtain information as to its existence.

Dermatologic work appeared in 1883, when Dr. J. V. Shoemaker of Philadelphia, read an elaborate paper, "Mechanical Remedies in the Treatment of Skin Diseases," to the Section of Practice of Medicine and Materia Medica at the annual meeting in Cleveland. He considered all the different applications and surgical operations on the skin from the dermatologic standpoint.

In 1884, in the same Section of Practice of Medicine and Materia Medica in Philadelphia, Dr. Louis A. Duhring read a paper on "Dermatitis Herpetiformis." He, for the first time, published his ideas concerning a group of bullous eruptions, which were wandering without a name between eczema, herpes and pemphigus. It is not necessary for me to make any comment on this work, all dermatologists in every country have accepted his views, and dermatitis herpetiformis type, Duhring, is an established group of dermatoses.

For some years I could not find that any papers concerning dermatology were presented to this ASSOCIATION, until in 1887 Henry J. Reynolds read to the Section of Medicine, Materia Medica and Therapeutics a paper on "A New Method of Producing Local Anesthesia of the Skin." The paper was one of great interest concerning the anesthetic action of cocaine by cataphoresis. He showed that with the application of a sponge saturated in a 5 per cent. solution connected

with the positive pole local anesthesia of an area of the skin, where a dermatologic operation had to be performed, could be produced.

At the same meeting Dr. L. Duncan Bulkley of New York, read a paper, "Infant Feeding, Especially with Reference to Subjects with Infantile Eczema," to the Section on Diseases of Children. This paper has remained a model on this important subject. Bulkley moreover read another paper on "The Treatment of Felon Without Incision," in the Section of Medicine, Materia Medica and Therapeutics.

As you see, at that time the dermatologic work could find no place; it was scattered in the different Sections without recognition.

It was at the meeting in Central Music Hall in Chicago in 1887, through the zealous and indefatigable work of L. Duncan Bulkley, it was determined by the general assembly to increase the number of sections, and the Section of Dermatology and Syphilography was formed. This was the first time that dermatology and syphilography obtained recognition from the ASSOCIATION, and very justly L. Duncan Bulkley was elected Chairman, and T. F. Dunlap of Danville, Ky., Secretary.

In Cincinnati, May 8, 1888, this Section was called to order for the first time. Dr. Bulkley, Chairman, read an interesting paper on "Syphilis as a Non-venereal Disease."

I beg to refer to a few words pronounced at that time by the Chairman, expressing plainly and thoroughly the scope of our Section of the AMERICAN MEDICAL ASSOCIATION. "We gather here today at the first meeting of the Section on Dermatology and Syphilography of the AMERICAN MEDICAL ASSOCIATION, and in a measure to celebrate the recognition of this branch of medicine as a special department by the great representative medical organization of America. It is therefore an occasion in which those interested in this department of study and practice should feel a peculiar interest, and should particularly rejoice, for it certainly indicates an advance in medical thought and liberality, a broadening of the field of work of our ASSOCIATION, and it is to be hoped a benefit to the profession and community. The present Section is organized for work for the practical consideration of topics related to diseases of the skin, and it is hoped that it will contribute greatly to making dermatology a more interesting and successful field of labor, not only to those particularly engaged in this line of practice, but also to the general practitioner, to whom this branch often presents unusual difficulties."

I am unable to express in a better way the scope of the work of this Section, and these lines given by my predecessor will remain as an unchangeable law.

The first meeting was an assured success; papers of scientific and practical value were read by Zeissler and Reynold of Chicago; Ohmann-Dumesnil of St. Louis; Corlett of Cleveland; Fleischner of New

Haven; Palmer of Louisville; Juler and Ricketts of Cincinnati and many others. Several discussions were opened on important topics, as the "Etiology and treatment of eczema," by Bulkley, and the "Limit of the period during which syphilis can be communicated by contagion or inheritance," by L. B. Bangs of New York. It would take too long to give even the titles of the papers, which were read and review the discussions, but there is no doubt that this Section at the first meeting did good and profitable work.

In 1889 the meeting was held in Newport, R. I.; L. Duncan Bulkley remained the Chairman and W. T. Corlett was elected Secretary. The Chairman opened the meeting with an able address on "Recent Advances in the Treatment of Diseases of the Skin." Discussions were opened, one by Wm. T. Corlett and Henry Fleishner on the treatment of *tinea tonsurans*, another by L. Duncan Bulkley on "The Indications for and duration of the Treatment of Syphilis." Interesting papers were read by J. V. Shoemaker, Fred Levisseur, George T. Elliott, Ephraim Cutter, Abbott Cantrell and many others, closing the work with a paper by Bulkley, "The Early Recognition and Treatment of Epithelioma."

At the annual reunion in May, 1890, in Nashville, Tenn., Dr. Bulkley was again Chairman, and W. T. Corlett Secretary. The first read an address on "The Relative Value of Mercury and Iodin Compounds in the Treatment of Syphilis," and the second spoke on "The Effect of Boracic Acid on the Skin." Dr. M. B. Ricketts of Cincinnati reported two cases of atypic herpes zoster gangrenosa, and a few remarks on dermatitis herpetiformis were made by Ravogli. No report was given by the Secretary for this year and not even the program could be found.

In the same way no report of the Section was given for the 1891 annual meeting, held in Washington, D. C. Dr. Bulkley was still the Chairman. He read an address entitled "Clinical Notes on Lichen Planus." A complete report of the year 1892 shows excellent work done by this Section at the meeting in Detroit. Dr. Bulkley was again the Chairman and Ravogli was elected Secretary *pro tempore*. Over 100 physicians visited our Section. Papers of great importance were read, opening with the address of the Chairman on "Recent Advances in the Treatment of Diseases of the Skin"; more than twenty different dermatologic topics were presented and discussed by the members present. At this meeting Dr. Louis A. Duhring was elected Chairman and Dr. W. H. Dunlap Secretary.

The place of meeting for 1893 was Milwaukee. An interesting address was delivered by the Chairman, Dr. Duhring on "The Scope of Dermatology," and over twenty papers on dermatologic subjects were read and discussed.

At the meeting in San Francisco in 1894, Dr. Ohmann-Dumesnil of St. Louis, was Chairman of the Section, and Dr. L. F. Frank of Milwaukee, Secretary. In 1895 Dr. E. Regensburger of San Francisco, was Chairman, and Dr. D. H. Rand of Portland, Ore., Secretary. No report of the work of this Section can be found in the JOURNAL for these years, and not even the programs appear in the records.*

In 1896, at the meeting of Atlanta, Dr. L. Duncan Bulkley of New York, was Chairman, and Dr. T. C. Gilchrist of Baltimore, Secretary. An interesting and elaborate address was read by the Chairman on the

"Newer Remedies used in Diseases of the Skin up to Date," referring to all new remedies and applications from his own practical experience. The program was one of the most important by reason of the selections of subjects and the work done by their authors.

It was at that meeting that I received from you the honor of being made Chairman of the Section.

Now at the celebration of the fiftieth anniversary of the ASSOCIATION, we have reason to congratulate ourselves for the work done by our Section since it was formed and recognized by the AMERICAN MEDICAL ASSOCIATION. The work which has been done is such as no other dermatologic society could do better. Our work is more of a practical character, and has the scope of placing dermatologic questions before the general practitioner and interest him in this medical branch. For many years dermatology has been for the generality of practicing physicians a *terra incognita*, and its study difficult or distasteful. But when we choose plain subjects adapted to the knowledge of the generality of practitioners, then we make this branch of medicine pleasant and interesting to all. Jonathan Hutchinson in his address, "The Future of Dermatology" at the meeting of the British Medical Association said, that "the aim of all true-hearted specialists was to break down the walls of specialism." This assertion has been happily repeated by Bulkley in his second address to this Section, saying that the Section on Dermatology and Syphilography is organized for work in the line of practical dermatology, and as a Section of the AMERICAN MEDICAL ASSOCIATION it should be attended by members who are not dermatologists, and subjects should be presented which are of practical interest and value to the general practitioner.

The study of dermatology is, in fact, so intimately connected with general pathology, that it is impossible to establish a rational treatment, without considering the skin lesion in reference to the physiologic and pathologic conditions of the general system. Dermatology has contributed much to the advances of general medicine. The study of the different morbid processes in the skin has increased the knowledge of the internal alterations, and has removed many erroneous ideas of the metastases. The morbid phenomena which occur in the skin are seen during life, and place the observer in a position to compare these, with what happens in the internal organs, which can be observed only after death.

If we consider, for instance, the group of herpes which have given origin to the myth of an herpetic diathesis, we find it clearly demonstrated to be in connection with the disturbances of the peripheral ganglia of the nerves. In the same way cases of nevi, leucodermia, atrophy of the skin and scleroderma, have been referred to conditions of peripheral neuritis. Many skin eruptions of the great family of the erythema originate from disorders of the vasomotor nerves. And again, that which produces this disorder of the vasomotor nerves has been found to be the toxins or toxalbumins resulting from an imperfect digestion, or from a stasis of the feces in the intestines, or from imperfect chemie changes in the metabolism of the tissues, acting as a poisoning agent on the center of the vasomotor nerves, causing erythematous eruptions. In the same way a large number of medicines are capable of producing eruptions of the skin which may be mistaken for almost any kind of dermatosis from a iodic acne to an arsenic cancer.

* NOTE.—None of the papers were ever received by the JOURNAL.—ED.

Often, in cases of gangrenous spots, or of localized erythema, we find the presence of sugar in the urine and today we know xanthoma diabeticorum as a manifestation of diabetes.

Since the discovery of the tubercle bacillus by Koch, it has been demonstrated that lupus vulgaris and other ulcers are only localized forms of the tubercular disease in the skin. It has also been shown that the tubercle bacillus can remain circumscribed in the tissue of the derma without producing infection. The infectious power, however, is not lost by the bacillus, which has for some years remained encapsuled in those tissues, and at any period we find that fresh lupus eruptions take place in old scars, healed long ago.

In lupus vulgaris multiplex, where many patches are present, we have some infection, and we find that potency of infection exists as we may have a rapid spreading of the lupus lesions in many regions of the body. The tubercle bacillus, however, remains in the tissues which it has affected, and for this reason the local treatment of lupus gives no anxiety as to the reproduction of tuberculosis in other organs.

Lupus erythematosus, which could not find a nosologic place, has been found to be a variety of tuberculosis of the skin, and has been associated with lupus vulgaris as a result of tuberculosis.

The action of tuberculin on the tubercular tissues could not be demonstrated in any other way than in the tubercular affections of the skin, and the first experiments with Koch's tuberculin were made on cases of lupus, showing the local reaction of the tissues invaded by the tubercle bacillus.

The combination of diseases has made clear many obscure points of pathology and the possibility of the existence of tubercular affections mixed with cancer is an assured fact, in lupus cancer.

Indeed, many simple granulomata of the face, or limited inflammatory processes, in time are changed to cancerous growths, due to cellular predisposition.

The knowledge of the parasites of the skin has greatly advanced general medicine, and, moreover, bacteriology has shown the local origin of the infection of so many diseases in the different organs composing the skin. The rôle played by the staphylococcus albus, aureus, etc., in the production of the different kinds of sycooses, in the furunculoses, in impetigo, the streptococcus in erysipelas, etc., show plainly the intimate relations existing between the general practitioner and the dermatologist.

The knowledge of syphilis, which takes so great a part in producing cutaneous lesions, is a portion of dermatology, which widely concerns the general medical practitioner. It refers to an immense field of important questions, which have to do, not only with the affected individual, but also with the happiness of his family. In many cases we can not find much in the history of the patient, and only by the condition of the skin and from other accompanying symptoms can we come to a conclusive diagnosis. In every stage of syphilis the skin is more or less involved, and it affords us the explanation of symptoms which could be mistaken for different affections. It is not necessary to remind you of the different affections of the various organs due to syphilis, which the general practitioner sees more often than the specialist. The advice often asked in reference to marriage, gestation, lactation, and the condition of the offspring, touch at first the general practitioner, and only afterward the specialist.

The therapeutics of diseases of the skin has shown clearly the necessity of connecting the skin lesions with the conditions of the general system in order to obtain decided results. With the exception of arsenic, which has a peculiar direct action on the eruptions of lichen and in some bullous eruptions, and of mercury for syphilis, we can not point out specific remedies in the therapeutics of the dermatoses. One of the most important points for the dermatologist is to institute a general treatment directed to correct the prevailing systemic disturbances, which are the cause of the trouble in the skin. We often see cases of nervous eczema which have been treated with external applications unsuccessfully, and only after a well directed internal treatment and a well adapted diet can it be brought to complete recovery. What I have said of this single instance can be applied to a large number of skin affections, which for a time have been regarded too much as purely local.

From the above considerations we see that dermatology can not be circumscribed within the limits of specialism, but it is one of the medical branches of much importance for the general physician and surgeon. THE AMERICAN MEDICAL ASSOCIATION having formed this Section has opened and widened the field of medical knowledge. It has placed within the reach of the general physician the study of dermatology, and has interested all practitioners in its study. In nearly all of the best medical colleges of this country dermatology and syphilography is now a special chair, and the students are compelled to pass examination in it. Clinical lectures on dermatology are delivered in many hospitals to the students, and the young physicians are now well acquainted with this medical branch. I am sure that the lack of knowledge of the diseases of the skin in this country, so lamented by Dr. A. R. Robinson in his address to the Section of Dermatology and Syphilography, at the International Medical Congress, in Washington, in 1887, has greatly diminished, and the AMERICAN MEDICAL ASSOCIATION has contributed its share by recognizing this branch among the Sections. I would now ask, through this great organization, that every regular college in the Union have the chair of dermatology and syphilography, with a final examination in these branches. This we will surely obtain when the physician realizes the imperative necessity of a knowledge of this branch.

From all I have said you can see that our Section has done good and important work. At the fiftieth anniversary of the ASSOCIATION, although scarcely ten years old, it shows a number of papers and discussions on interesting dermatologic subjects.

There is no doubt that the work of the American dermatologists has been recognized in the scientific world, and every year important treatises, interesting observations and scientific pamphlets are issued from this country, so that American dermatology is second to no other.

By placing this study within the reach of all practitioners, by compelling the students to pass examinations in dermatology, breaking this wall of specialism, we are sure that the future of dermatology will be much more brilliant and important. From the past we can judge of the future: if this Section in less than ten years has achieved so much, we can foresee that in the future it will be of greater honor to the members, of greater importance to the general physician, and of greater benefit to suffering humanity.

MODERN METHODS OF MEDICAL INSTRUCTION.

In response to a toast at a dinner of the Rush Medical College.
March 17, 1898.

BY HENRY BAIRD FAVILL, M.D.
CHICAGO, ILL.

Mr. President and Gentlemen of the Faculty:

My interest in this matter is not greater than my marvel at the enormous advance which has occurred within the short space of years, since 1880, when my medical college experience commenced. And yet in drawing the comparison, which so forcibly presents itself, I must declare that it is not to the discredit of the early day, any more than that day was a rebuke to its predecessor. I believe that you will agree with me, that medical education offered to students at that day was as nearly abreast of the education possible for them, as is our present exhibition an approach to the present possibility. The great difference in spirit which strikes me as occurring in respect to medical education in general, lies in the attitude of the public toward the profession or more exactly of the State toward the medical school. In this the change is very pronounced and I believe the advancement is very clear. It is on the whole a matter for congratulation both to the schools and the profession at large, that society has seen fit to demand that we require of the medical graduates as good an education, as we offer. That this change has been instigated by the profession, is to its credit, and does not qualify the advantage so far as society is concerned. That the means and methods to this end have been at times unreasonable, inconvenient, and are in many respects meddlesome, is but a passing annoyance as compared with the final advantage, which resides in the fact, that while the public is properly protected the medical schools are relieved of the embarrassment of illegitimate competition, and the entire process operates as a measure whereby there is culled the unfit material.

When we come to consider our own more specific interests as educators we would designate amongst many improvements three features in particular which claim our earnest consideration: First, the laboratory; second, the clinic; third, the recitation.

Of the laboratory too much can not be said, little need be said. It represents the utmost development of the educational idea. To have incorporated it in our own affairs to the extent possibly of disproportionate development credits us naturally with the desire to be entirely *en rapport* with the march of education in every department.

To one who has not had the advantage of a technical laboratory training, but whose interest and ambition have led him to the acquirement of lame and half satisfying methods in furtherance of his desire for power, the idea of laboratory training is most alluring. Recognizing this, it suggests to me qualifications upon which I wish to comment. The laboratory factor is liable to over-estimate in two directions: 1, by many of those who have had no laboratory experience, to whom the revelations of the laboratory assume an exaggerated importance, in consequence of the mystery which surrounds them; and on the other hand, 2, by those whose training assures their position as laboratory experts and whose occupation is of that fortunate stripe, rare in medicine, which results in the demonstration of things. These men for whom I have the most profound respect, naturally regard

things from the laboratory standpoint, and being engrossed in it and trained to the primary idea of truth as dependent upon demonstration, are not quite prepared for the consideration of subjects which have as yet no laboratory point of view.

Many of these men have neither the inspiration for, nor the tolerance of the field of speculative medicine, within which, however, occur those projected lines, along which the correlation of knowledge for its practical application must occur.

These two reservations are of minor significance except as considered in the light of curriculum, and serve to emphasize merely the indisputable fact, that in producing a balanced result, medical reasoners, as complementary to medical investigators, are indispensable.

Our encomium upon the laboratory can not be diminished when we take up the subject of the clinic. Here there opens before us the hope of the future. Though the clinic has always existed, it is today in form and in spirit, quite different. The general clinic with the full amphitheater, though it remains in the form, is no longer the arena for the demonstration of the prowess, or for the personal aggrandizement of the professor. It is solely for the purpose of bringing the student in intimate contact with conditions which are to be in the future his perplexities, and as such is capable of being made most effective. The thing, however, which we earnestly crave is the clinic for small classes, the smaller the better.

The first advantage claimed for this, is that the student being permitted to examine the patients, and required to make a diagnosis, becomes immensely strengthened. This is in a measure true, though I believe those who are teaching clinically would agree with me that even this is subordinate in importance to the fact, that the interchange of thought between the students and instructors, in immediate presence of the subject, is usual, to a degree which in a large class is impossible.

I approach that which is to me at this moment of somewhat more immediate interest, the recitation.

In this innovation, we find the most signal departure from time honored method, and properly administered the most promising foundation for broad education. I repeat, properly administered, because I am positive that improperly administered it is a source of weakness. I stipulate, among many things, four which are primary to its propriety.

First, that the classes should be small, because we accomplish thereby, in this compactness, manageability, which includes the greater facility in determining the current acquisition of the students. And second, I would stipulate that the text employed be various. It is necessary for obvious reasons to have a uniform text, designated as a skeleton upon which to build, but I am emphatic in my declaration, that students should be encouraged to seek the information preparatory to the recitation, from all available sources, and that this exercise should be the meeting ground upon which should be thrown all possible side lights, and upon which should be harmonized, as far as possible, whatever apparent conflict may arise. Thus we lay the foundation for breadth of view.

I approach the third requirement with hesitancy, yet I trust even by my colleagues who are touched by this, that I shall not be misunderstood. I believe that the instructors should be men of experience, more or less according to the subject involved, but

with the firm conviction that the more experienced the better. I am sure that no man is so capable of illuminating the obscure path, as one who has been lost in it.

The combination of intelligence and sympathy which results from such experience is invaluable to the teacher. To have these conditions satisfied ideally, particularly at the outset of the new regime, is impossible. To build toward them is imperative.

To this end I suggest, that every effort be made to retain in the service of the institution, the men who justify their relation to it, and at every hand to so dignify their relation, that the feeling of responsibility shall reinforce the interest which may flag under neglect.

Fourth, and most important, comes the question as to the relation of the instructor to his class. Shall he be a critic whose function begins and ends with an inquisition as to the presence and industry of his students as evidenced by their ability to recite, which function I would not underrate, or shall he be in addition, an expounder of the subject?

That the latter should be admits of no question.

In the first place because medical literature is unfortunately obscure and needs intelligent presentation. In the second place medical information is shifting and needs a current commentator for the correction of the misconceptions of the past. These facts being beyond dispute, the question simply remains, shall this important work be done by the instructors or by the professor at large, if I may use the term?

Assuming the competency of the instructor, I unhesitatingly select him for the function for two reasons: First, because with the assumed limited class one secures the psychologic advantage of man to man contact. Second, because the essence of instructive analysis is interrogation, which implies a slowness of procedure, and a quality of relationship, which is possible only in the class room.

It might be queried in the light of all this disposition of labor into the departments of subordinate instructors, what becomes of the chief faculty. Are they, in the new adjustment, mere figure-heads? I confess that in the extravagance of expression which one sometimes hears in discussion of the new regime, it might so appear. To me the assumption of higher achievement through the working out of the processes just discussed, implies a field of usefulness for the heads of the departments enormously elevated and dignified. It is true that much of the detail of their labor is cut off. It is true that much of the prominence of a certain kind is removed, but I call your attention to these facts.

In medicine as in no other field of research, there is at present no such thing as fixed authority. The dictum of no man is better than another's, except in so far as the depth of his research or breadth of his experience and the integrity of his reasoning process, justifies it. The profession has not to deal with an accumulated mass of settled fact. It has to deal with an enormous reservoir of knowledge, into which flow streams of more or less disconnected observation. But for every drop of fixed knowledge, there is a flood of interpretation, and upon the selection of the instrument of interpretation will rest the value of the store which the student may acquire.

Is the student about to be graduated capable of being his own interpreter? Is he sufficiently in possession of the facts, and has he the perspective to enable

him to wisely select the theory and adopt the practice under such conditions? Assuredly, most assuredly not. Here then lies the highest prerogative of the department head.

To him let it fall to summarize knowledge, to analyze experience, to harmonize conflict. And in so far as he is fortunately possessed of personality, to so impress himself and his wisdom upon the students that he utter for their provisional guidance a working hypothesis, as indispensable here as elsewhere, which shall bear the stamp of the organic body, which launches its graduates.

ORIGINAL ARTICLES.

A CASE OF MENINGOMYELITIS, RESEMBLING IN SOME RESPECTS LANDRY'S PARALYSIS, WITH SPECIAL REFERENCE TO TUBERCULOUS MENINGOMYELITIS.

FROM THE WILLIAM PEPPER CLINICAL LABORATORY, UNIVERSITY OF PENNSYLVANIA.

Presented to the Section on Neurology and Medical Jurisprudence at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY WILLIAM G. SPILLER, M.D.

PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM IN THE PHILADELPHIA POLYCLINIC; ASSOCIATE IN THE WILLIAM PEPPER CLINICAL LABORATORY, PHILADELPHIA, PA.

The case which is reported in this paper was studied clinically by Dr. James Hendrie Lloyd, during one of his terms of service at the Philadelphia Hospital, and the clinical notes were taken by him.

J. H. A. was 40 years of age at the time of admission to the Philadelphia Hospital, June 27, 1894. He gave no history of hereditary disease, and stated that previous to his present illness he had always been in good health, with the exception of a constant sick headache, which he had had since the age of 3 years. This was sometimes accompanied by vomiting. No treatment gave him relief. During the year previous the headache had been growing less severe, and during the two months before his entrance into the hospital it had ceased entirely. He denied having used alcohol, or having had venereal disease. In earlier life he had been a school teacher, later a grocer.

Eight weeks before his admission, a drunken man had entered his house and smashed a lamp. He had become greatly excited by this, and had had a severe nervous shock, as he expressed it. Inquiry elicited from his brother the information that the patient had had domestic trouble, and that this person said to be a drunken man was in reality the patient's intoxicated wife. There was evidently at this time a mental disturbance, due possibly, as indicated by the microscopic findings, to cerebral meningitis or bacterial poisoning. A few days later he says he had an attack of stomach trouble, and yet he could give no history of the symptoms of gastric disease. He had had no pain, had not vomited, and had been able to eat anything with impunity. Dr. Lloyd obtained from his friends the statement that his condition resembled that of typhoid fever. He was sick in bed for one month and recovered at the end of that time, but did not work. Two weeks later he had an attack of nervousness, as he expressed it, in which he trembled very much. During the two weeks previous to admis-

sion to the hospital, his arms became weak and he was unable to dress or feed himself. At nearly the same time weakness of the legs was noticed. He had absolutely no pain. When he sat down he could not rise without assistance. His bowels were regular and his appetite good. The report of the examination made by Dr. Lloyd at the time of admission, June 27, 1894, is as follows: The patient was found to have inability to pass his urine and it was necessary to catheterize him; later he developed incontinence.

He was a thin, anemic man, apparently not 40 years old. His speech was rather slow and not well articulated, and had been of this character for ten days, according to his statement. His eyes were injected. Spasms of the orbicularis palpebrarum were frequent. There was no nystagmus. His pupils were equal and responded to light and in accommodation. The visual fields were normal. Hearing was not impaired. His tongue was protruded in a straight line, was heavily coated, and presented some fibrillary twitchings. His chest was poorly developed, though the respiratory expansion was normal. The apex of the right lung presented dulness posteriorly, increased tactile fremitus and crackling râles. The left apex posteriorly also gave some dulness. The pulse was rapid and weak, and the arteries were very much thickened. The apex beat of the heart was in the fifth interspace outside the nipple line, and easily seen. A murmur, not transmitted, presystolic in time, was detected at the apex. The abdomen was scaphoid in shape. The liver and spleen were of normal size. Voluntary flexion and extension of the left upper limb at the elbow were impossible, and much impaired at the wrist. Pronation and supination of the left forearm were imperfect. Voluntary flexion was possible at the right elbow, but the power of extension was lost, otherwise the conditions were the same as in the left arm. The pectoral, supra- and infra-spinous muscles were intact. The dynamometer registered 20 in both hands. All the voluntary movements of the lower extremities were imperfect. There were no areas of anesthesia. The knee jerks were exaggerated, but sluggish; the muscle jerks were also exaggerated; ankle clonus was obtained but soon exhausted, wrist clonus was also observed. On mensuration the following figures were noted:

	June 27.	July 8.
Right upper limb at shoulder . . .	13 inches	13 inches
Right upper limb at axillary fold .	7 $\frac{1}{2}$ "	7 $\frac{1}{2}$ "
Right upper limb at mid portion of arm	7 $\frac{1}{2}$ "	7 $\frac{1}{2}$ "
Right forearm	8 "	8 "
Right lower limb at thigh	13 $\frac{1}{2}$ "	11 $\frac{3}{4}$ "
Right lower limb at calf	10 $\frac{1}{4}$ "	7 $\frac{3}{4}$ "
Left upper limb at shoulder	13 "	13 "
Left upper limb at axillary fold .	7 $\frac{1}{4}$ "	7 $\frac{1}{4}$ "
Left upper limb at mid portion of arm	7 $\frac{1}{4}$ "	7 $\frac{1}{4}$ "
Left forearm	8 "	8 "
Left lower limb at thigh	13 $\frac{1}{2}$ "	11 $\frac{3}{4}$ "
Left lower limb at calf	10 $\frac{1}{4}$ "	7 $\frac{3}{4}$ "

The electric reactions to the faradic current were normal, to the galvanic they were as follows:

Forearm flexors	} ccc > acc
Forearm extensors	
Forearm pronators	
Biceps	ccc < acc
Pectoral	ccc > acc
Lower limbs peroneal	} ccc < acc
Anterior tibial	
Gastrocnemius	
Flexors of legs	ccc = acc
Muscles of thighs	ccc < acc

Considerable atrophy was thus observed in the lower limbs, which developed within two weeks, and reaction of degeneration, *i. e.*, change in the formulæ, was noticed in some of the muscles of both upper and lower limbs.

During the early part of July the patient appeared to be improving and regained considerably the power of moving the upper extremities, but during the latter five or six days of the month his disease took a decided turn for the worse. The temperature rose to between 101 and 102, and the hurried, labored respiration gave evidence of a marked pulmonary affection. Satisfactory physical examination at this time was impossible on account of the low condition of the patient. Death occurred Aug. 1, 1894.

The autopsy was made Aug. 2, 1894, by Dr. W. S. Carter, the condensed report of which is as follows:

The body was much emaciated. The entire vascular system had undergone a premature senile change, which in a man of forty years was remarkable. The aorta and other vessels, including the circle of Willis, were markedly atheromatous. The heart was hypertrophied. The leaflets of the mitral and aortic valves were thickened. The orifice of the mitral valve measured ninety-five mm., that of the aorta sixty-eight mm. The kidneys were small, tough and granular, presenting the appearance of interstitial nephritis. Decided catarrhal pneumonia was noticed at the base of the left lung. There were evidences of tuberculosis in various parts of the body. Tubercles were found in the lungs, spleen and liver. The bronchial, retro-peritoneal and mesenteric glands were enlarged and yellowish. There were some evidences of tuberculous meningitis. Apart from some congestion and perhaps slight adhesion of the pia, together with the atheromatous condition of the vessels previously mentioned, no macroscopic anomaly was detected.

The microscopic report by the writer is as follows:

In the lumbar region a round-cell infiltration, very similar to that seen in syphilis, is found within the meninges and spinal roots, and is somewhat more extensive here than at any other portion of the cerebrospinal axis. The round cells are more numerous in certain parts of the pia; they are also found about some of the vessels of the cord, and indeed here and there where no vessel may be observed. The vessels of the meninges and spinal cord are distended. Within the white matter, more especially in the anterolateral columns, numerous small spaces are found which possibly are the result of destruction of nerve fibers. Certain histologists have regarded these spaces as artefacts, others have been unable to accept this view. They have been noted especially in cases of pernicious anemia and in paralysis agitans. Axis cylinders may be found in many of these spaces, and in some they are surrounded by a medullary sheath, though in general the medullary sheath is swollen and transparent. Homén¹ has also described these spaces in the dog's cord in secondary degeneration.

Many of the motor cells of the anterior horns, especially in the lumbar region, are tumefied, rounded off, without protoplasmic processes and contain vacuoles. Some present a more normal appearance. In some the nucleus has taken a peripheral position. Marinesco² regards this displacement of the nucleus as very important. As a rule, the nucleus occupies the

¹ Homén: Atlas der pathologischen Histologie des Nervensystems Part VI.

exact center of a nerve cell, for it is at this part that nutrition of the cell is greatest. The migration of the nucleus, according to his view, is an attempt on its part to reach a portion of the cell where nutrition is better.

The vacuolization of nerve cells has given rise to endless discussion. Hitzig³ has recently stated that he regards it as a manifestation of disease; others, and among them Nissl,⁴ look upon this as a post-mortem change. But it has been stated that even if the latter view is correct, it is probable that this alteration takes place during the process of hardening of tissue in the chromic salts, more commonly in diseased cells than in normal (Leyden and Goldscheider).⁵ This view seems acceptable, for in spinal cords in which there has been no reason to suspect organic changes one does not find such vacuolization as seen in this case. The method of Nissl could not be employed, as Müller's fluid had been used as the hardening agent. Nissl⁴ expresses the opinion that nerve cells may be restored as long as the nucleus has not been greatly altered. The cells in this case had apparently not reached this critical stage.

I have been surprised to find so many amyloid bodies, especially within the lumbar region. It is well known that these occur normally in the central nervous system, but usually in more limited numbers, except perhaps in the olfactory lobes. When stained with any of the ordinary solutions of alum-hematoxylin they are of a light purple color, homogeneous in appearance, of various sizes, round and considerably larger than the nuclei of the neuroglia cells. These bodies, as in this case, are especially numerous in the posterior columns, within the septa, near the vessels, about the central canal, and especially within the zones of Lissauer. They extend a short distance into the posterior roots and cease here abruptly. Redlich has studied these formations and states that they give the amyloid reaction with Lugol's solution and sulphuric acid. This is an observation which the writer has been able to confirm. Redlich does not regard them as of the same nature as the amyloid bodies of the prostate gland, or as ordinary amyloid infiltration, and the writer also has not been able to obtain the characteristic reaction with certain stains usually employed for amyloid substance. Redlich regards these bodies as derivatives of altered neuroglial cells; other histologists look upon them as formed from the axis cylinders. Homén¹ states that they come from degenerated fibers. They indicate a chronic, retrograde process. I have found them in large quantities in cases of tabes, syringomyelia, syphilis, senility, etc. It was with some surprise, however, that so many were observed in this case, for the history indicated rather an acute process, and the man was at that period of life in which they do not usually occur in such numbers. The patient had sclerosis of the vessels, but in the lumbar region the small arteries and veins present no notable thickening of their walls as is seen in the cervical region and at the base of the brain, and it is especially in the lumbar region that the amyloid bodies are so numerous. It does not seem reasonable to suppose that the arterio-sclerosis accounts entirely for their formation, but we may regard them as representing some form of degenera-

tion not entirely acute, and possibly in connection with the tuberculous process.

In the thoracic region the findings are similar to those of the lumbar; in one portion near the periphery of the cord, peculiar, irregularly formed bodies, stained red with the carmin, are observed. They do not resemble cells, and may possibly be swollen fragments of axis cylinders or swollen neuroglial cells. Here and there in the gray matter of the thoracic region small hemorrhages are noticed. Some few of the vessels within the cord have thickened walls which have undergone hyaline degeneration. By the method of Weigert, apart from the many red blood corpuscles observed within the meninges, and the thickening of the vessels in the upper regions of the cord and at the base of the brain, nothing pathologic would be suspected.

In the cervical region in some of the small meningeal arteries, the intima is much thickened and the media and adventitia are infiltrated with round cells, but there does not appear to be a reduplication of the elastic membrane. The walls of the small meningeal veins are also thickened, and in some the lumen is much reduced. Throughout the meninges and not confined to the cervical region, there is an abundance of blood pigment and red blood corpuscles. The round cells are found scattered singly through the tissues or collected in groups, but the infiltration is only of moderate degree. In one section, for example, a collection of cells mingled with red blood corpuscles may be noticed about one of the anterior roots. Such a condition when existing in the lumbar region may explain, in part, the symptoms of weakness and the increased though sluggish reflexes. The vessels within the spinal roots are much distended, cellular infiltration is noticed in these parts and, to a moderate degree within the septa, sometimes spoken of as pia, though the connection of these septa with the pia has been disputed (Lenhossék,⁶ Edinger⁷). Small collections of blood pigment are found within the cord. The number of the capillaries of the anterior horns appears greater than normal. Hemorrhage is also found within the gray matter. The method of Marchi reveals much pigment within the ganglion cells, but nothing which could be considered distinctly pathologic. This method is valuable for a study of the development of pigment, as the fatty nature of this substance causes it to be colored black by the osmic acid.

At the base of the brain, to which attention has been directed on account of the history of spasm of the obicularis palpebrarum, a moderate degree of round-cell infiltration has been found which may possibly have irritated some of the fibers of the seventh nerves. Similar accumulations of blood pigment and corpuscles are found at this level.

In those portions of the cerebrospinal axis which have been kept two years in Müller's fluid peculiar bodies have been noted. They are not to be observed to any notable degree in any portion of the cord which has been preserved in alcohol. They are small, round or oval, stained deeply with Delafield's hematoxylin and with thionin, even more deeply than do the nuclei of the round cells. They are intensely stained at the periphery, while the center is only faintly colored. These bodies are found within the cord, within

the neuroglial trabeculae, along the small vessels, and within the pia, especially at its junction with the spinal cord, where they are arranged in long rows, although they are also found in groups. The fact that they are only to be seen, to any notable degree, in tissues preserved in Müller's fluid proves that they could not have been in causal relation with the morbid process. It has been my experience that Müller's fluid does not arrest the development of all low forms of life. Prof. A. C. Abbott, of the University of Pennsylvania, has given his opinion in regard to these bodies as follows:

"1. They are not spores, because they stain readily. Spores are also highly refractive.

"2. Unless they came from extraneous sources spores would not be likely to occur within the tissues.

"3. They are of oval shape. The irregularity in their size, the peculiarity of their staining, and more especially the appearance of budding that is frequently noticed, would seem to support the opinion that the bodies found here belong to the group of blastomycetes (yeasts).

"4. The peculiarity of staining consists in the accentuation of the enveloping membrane over the body of the cell.

"5. They can not be micrococci."

I have frequently found similar bodies in other material hardened in Müller's fluid.

Sections examined from the brachial plexus, the peroneal and sciatic nerves, show no notable degeneration of nerve fibers. Round-cell infiltration of very moderate degree is observed within some of the nerve bundles and their sheaths.

In view of the importance of determining the presence or absence of micro-organisms in this case. I requested Drs. Kneass and Taylor of the Pepper Laboratory to make an examination with this object in view. They have been unable to find any organic forms not already mentioned. A number of sections have been stained by the writer, in the hope of finding the tubercle bacillus, or some other form of micro-organism, but success has not crowned his efforts. Recently most interesting experiments have demonstrated that the injection of bacterial toxins into the lower animals may produce neuritis and meningomyelitis. Such experiments have been made by Claude,⁸ Homén and Laitinen,⁹ Marinesco,¹⁰ and Remlinger.¹¹ Work bearing on this subject has been done in our country by Welch and Flexner.¹²

We may say in regard to the microscopic examination of this case that the condition is one of meningomyelitis, involving also the membranes at the base of the brain, with very imperfect evidences of neuritis. No cutaneous nerves were obtained for examination. Arterio-sclerosis, of not recent origin, is found in the vessels at the base of the brain, and in the smaller vessels of the upper part of the cord. The meninges covering the spinal cord and at the base of the brain are infiltrated by round cells and contain much blood pigment and many blood corpuscles. The motor cells of the anterior vacuoles and horns are swollen and rounded off, and many contain displaced nuclei; many however show no alteration. Round-cell infiltration and capillary hemorrhages are found here and

there in the spinal cord. The lesions are rather more intense in the lumbar portion; in this part also, where the arterio-sclerosis is not marked, there is great excess of amyloid bodies. No tubercles, no giant cells and no low organic forms, except the blastomycetes, are found anywhere. What is the cause of this process? The writer is inclined to attribute it to tuberculosis.

With such a clinical history as the one given in this paper, it is not surprising that the diagnosis of Landry's paralysis was uppermost in Dr. Lloyd's mind, although there were certain atypical features in the case. It was undoubtedly a morbid process affecting the motor portion of the nervous system, and producing no symptoms from involvement of the sensory side. It could hardly be a neuritis as the word is usually understood, unless we mean that the cells of the anterior horns of the cord were chiefly diseased, and the peripheral part of the neurons only secondarily affected. Motor neuritis without involvement of sensory fibers does occur, as may be seen from the case of Dejerine and Sottas,¹³ specimens from which have been given the writer. One would think twice, however, before making the diagnosis of pure, primary motor neuritis. It seems probable that the Charcot-Marie type of muscular atrophy is often a motor neuritis, and yet this is not acute or subacute, as was the process in the present case. This patient had no disturbance of sensation, no sensitive points along the line of the nerve trunks, and the exaggerated though sluggish knee jerks were not in favor of neuritis. Could the case have been a subacute form of anterior poliomyelitis? There was much in favor of such a view. The motor paralysis, the reaction of degeneration, the absence of sensory symptoms, even the vesical paralysis, could all be easily explained by such a theory. But exaggerated reflexes do not belong to this disease, and there was evidently some process here which both irritated and weakened the peripheral motor neurons. If we turn to the paper of Diller and Meyer¹⁴ we find given as the cardinal points of Landry's paralysis: "1, flaccid paralysis of the muscles, spreading rapidly from one point over the rest of the body, generally beginning in the legs, but sometimes following the reverse order, as in the French zoölogist Cuvier; 2, absence of muscular atrophy and of electric reaction of degeneration; 3, tendon and superficial reflexes absent; 4, sensibility not, or only slightly impaired; 5, sphincters, as a rule, intact (exceptions rather frequent); 6, a criterion has been the absence of an anatomic lesion."

We will see that the very first requirement can not be met. The paralysis probably was not flaccid. The duration of the process from the time paralysis was first noticed until death occurred was about six or seven weeks. The upper extremities were first paralyzed, but very soon the lower were also affected. The patient was thin and anemic, and yet muscular wasting developed very rapidly in the lower limbs. There was reaction of degeneration *i. e.*, inversion of the formulae, in all the muscles of the lower limbs, and in the biceps of the upper. The tendon reflexes not only were not absent, but were exaggerated and sluggish. As a case of Landry's paralysis the symptoms were atypical.

The findings permit a pathologic diagnosis of men-

ingomyelitis of moderate intensity. Is it possible to reconcile the symptoms observed during life with such a process? How shall we explain the absence of sensory symptoms? The clinical picture was not that of meningitis. In this disease, however, one must be prepared for the unexpected. The meningitis was only of moderate intensity in the case under consideration, and it is probable that the irritation was not sufficient to produce sensory symptoms. It may be that the central nervous system was overpowered by some toxin brought through the circulation, and that the symptoms were due more to myelitis than to meningitis. That certain poisons act on nerve cells and nerve fibers in such a way that they produce functional changes before organic alteration can be detected, even by the best technique, is a view which is probably correct. Wagner¹⁵ has called attention to gastro-intestinal disturbances as a cause of polyneuritis and psychoses, probably produced by the action of some poison absorbed from the gastro-intestinal tract. Neuritis after infectious diseases is probably chiefly due to the toxins produced by the bacteria. Still earlier, Dercum¹⁶ has spoken of the influence of auto-intoxication in psychoses, and more recently Allen McLane Hamilton¹⁷ and Van Gieson¹⁸ have written papers on this subject. It is doubtful whether we should find lesions in all such cases. But there was something more than functional disturbance in this case, for many of the motor cells of the anterior horns, especially in the lumbar region were much altered. The atrophy and reaction of degeneration were most evident in the lower limbs. A meningitis of moderate degree not infrequently fails to produce symptoms. The typhoid condition and the mental state preceding (Cavasse¹⁹) may have been due to such alterations as have been detected throughout the body. This patient had general tuberculosis; this alone would account for the resemblance of certain of his symptoms to typhoid fever.

Anyone who examines the literature will find a number of atypic cases of myelomeningitis, especially of the tuberculous variety. We may refer in this connection to Schultze, Goldscheider, etc.; Schultze²⁰ says that every symptom of meningitis and myelitis, even in histologically demonstrable cases of these affections, may be absent and the clinical picture may be one of acute ascending paralysis. It must be remembered also that meningitis in the adult may present a more atypic picture than in the child (Cavasse l. c.). Chantemesse (quoted by Cavasse) has written a thesis on the atypic form of tuberculous meningitis. Oppenheim²¹ tells us that an extensive purulent cerebrospinal meningitis may be without symptoms, and he speaks of the polymorphism of acute meningitis. The spasms of the orbicularis palpebrarum, the exaggerated but sluggish knee jerks, the fibrillary tremor of the tongue, are explained by the findings. There was no reason for suspicion of syphilis from the history and condition of the patient. Can we find any ground for believing that this case may be considered as possibly one of tuberculous meningomyelitis?

The involvement of the spinal cord in the tuberculous process has been known for many years. Among the early writers on this subject mention may be

made especially of Liouville.²² Erb,²³ in 1876, remarked that tuberculous spinal meningitis is not uncommon in connection with the basal form. Schultze²⁴ also has regarded the tuberculous spinal meningitis as by no means rare, and the association of it with the basal form as the rule in the adult. This view is held also by recent writers (Oppenheim,²⁵ Goldscheider,²⁶ etc.). Miliary tubercles were not found in the cord in all of Schultze's cases. His statements made in 1880 are to the effect that miliary tubercles are much less frequent in the spinal membranes than in the vessels and membranes of the brain; according to him, the posterior portion of the cord is the part most affected, although when the process is severe the anterior part of the cord may also be involved. The cord proper takes part in the morbid process, and the findings consist of edema, swelling of the axis cylinders, moderate tumefaction of the ganglion cells, more homogeneous appearance of the neuroglia, with more intense coloration under the action of stains, and cellular infiltration of the peripheral portions of the cord, chiefly noticeable in the lateral and posterior columns and in the thoracic and lower cervical regions. Cellular infiltration is common in the septa, and the cells may collect so as to form small tubercles. Small hemorrhages are frequently found. The roots present similar lesions.

Williams,²⁷ also, at an early date reported cases of cerebrospinal tuberculosis in which he found round-cell infiltration of the arachnoid, pia and cord. In two of his three cases it is stated that distinct miliary tubercles were not observed in the cord, although in one of these two cases they were found in the brain.

Goldscheider²⁸ has published a most interesting case. Violent contractions were observed in the muscles of the arm and forearm, shoulder and breast, while movements of the hands and fingers were free. There was lack of power and the reflexes were increased in the upper limbs. Sensation was normal. The patellar reflex was exaggerated. The only pain felt was that due to the violent contractions. At the autopsy in this case extensive pulmonary tuberculosis was observed. In the fresh state nothing was seen in the cord, oblongata or brain, but after the hardening the pia on the anterior part of the cord, from the fourth cervical to the first thoracic segment, was found to be moderately thickened and infiltrated with round cells. The anterior columns and periphery of the cord were also invaded by the round cells. The condition is described as anterior myelomeningitis. Similar cells were found within the anterior roots. Nothing abnormal was observed outside of the area mentioned, except a diffuse descending degeneration of moderate degree in the anterior columns. There was no tuberculous basal meningitis and no vertebral caries. No microorganisms of any kind could be detected and there were no signs of syphilis. This irritation of the anterior roots was supposed to have caused the contractions and exaggerated reflexes. The cervical meningomyelitis was thought to be tuberculous.

The tuberculous leptomyelitis, according to Raymond,²⁹ is not as rare as one might think. The diffuse

infiltration is much more common than are the large spinal tubercles, and it has not attracted the full attention it merits, as it easily escapes detection. Few writers, indeed, have spoken of this infiltrating form. In very many cases where tuberculous patients have died from acute generalization of the process, or even, perhaps, from slower development, an infiltrating leptomylitis may be found. Even though with the naked eye the cord in certain cases appears sound, the microscope often reveals tuberculous lesions. The tuberculous leptomylitis may exist with similar lesions in the brain, but it may be alone. It is quite probable that the nervous symptoms which occur in the course of tuberculosis may be attributed to this complication, at least in a certain number of cases. He has in mind the neuralgia, myalgia and hyperesthesia, which form part of the ordinary symptoms of chronic or acute phthisis. The lumbar region is the portion usually most involved in the tuberculous process. Raymond divided tuberculous meningitis into the chronic and acute forms, and the latter still further into the infiltrating (or diffuse) and the nodular varieties.

In the diffuse form the miliary tubercles are rare, and in some cases it is only by chance that such a tubercle is found in a section. It is difficult to distinguish the infiltrating tuberculous myelitis from the early stages of the simple acute form, if some miliary tubercles are not observed. He described a case of Pott's disease in which, in addition to chronic meningomyelitis, the appearance of more acute changes with hematomyelia were noted. The dura, arachnoid, pia and spinal roots were infiltrated with leucocytes, in some places large groups of round cells were noticed. At no part of the cord proper or pia were specific tuberculous lesions observed. The arachnoid was thickened and infiltrated, and at the portion corresponding to the caries of the vertebræ contained tubercles with giant cells. Specific lesions were also found in the dura. Expressed in a few words, it may be said that this patient had slight diffuse chronic leptomylitis, associated with an acute form of the process, and that this was known to be tuberculous from other findings. In the dura and arachnoid specific lesions were present.

In the report of a case of meningomyelitis by Raymond in the *Revue de Médecine*, 1886 (Case No. 2), the statement is made that no miliary tubercles were found with the naked eye or with the microscope. Congestion of the vessels and diffuse round-cell infiltration, slight thickening of the meninges, some swollen axis cylinders, obliteration of the central canal, tumefaction of the ganglion cells were observed. He says: "It is a diffuse general leptomeningitis of a diffuse and infiltrating form, evidently of tuberculous origin, as the clinical history shows, only this meningomyelitis has no characteristic anatomic features."

A still more recent writer on spinal tuberculosis is Haskovec.³⁰ He reports the following case from Charcot's clinic: The patient had phthisis but no evidence of syphilis. The nervous symptoms began with tingling in the feet, legs and anterior part of the thighs associated with some weakness in the lower limbs. After the lapse of a few months the legs became so weak within a few hours that the patient was unable to stand, and retention of urine and feces was observed. The paralysis in the lower limbs was flac-

cid and almost complete. This abrupt development of paralysis has also been noticed in tuberculous meningomyelitis by Hoche.³¹ It is a frequent sign of spinal syphilis.

There was anesthesia of the lower limbs and lower part of the trunk in Haskovec's case, but no spontaneous pain and no fever. The upper limbs were not at first affected. The entire duration of the process was about four months. Leucocytic infiltration was found in the meninges, anterior and posterior spinal roots and cord, and especially within the septa and about the vessels. The neuroglia was proliferated. Disseminated tubercles were also observed. Examination was only made of the cord and sciatic nerves, but clinically there were no symptoms which pointed to cerebral involvement. Degenerated fibers, capillary hemorrhages and congested vessels were found in the cord. Haskovec could not succeed in staining the tubercle bacilli or any other micro-organism. He attributes the early numbness and weakness in the feet to the congestion of the meninges and the slight irritation of the posterior roots. This was essentially a case of spinal tuberculosis, for, although the base of the brain was not examined, no clinical symptoms had been observed which indicated cerebral involvement. There may, nevertheless, have been a latent basal meningitis. The case has many features similar to the one which forms the subject of this paper, though differing from it in certain details.

The thoracic region of the cord is the portion usually affected, according to Haskovec. He gives statistics from observations made in Prague. In 2090 autopsies on tuberculous patients the brain was found affected by the process in 100, brain and cord in 9 and in 6 of these cerebrospinal meningitis was found; the cord was affected in 12 cases, and in most of these caries of the vertebræ was observed. His statement in regard to the frequency of the process is contradictory to Raymond's, for he says that tuberculosis of the central nervous system is rare.

Haskovec states that until the time his paper was written, the tubercle bacillus had not been stained in any of the cases of nodular and infiltrating spinal tuberculosis which he had quoted, although it had been found in solitary tubercles. Schamschin says the bacilli were found in all his cases of tuberculosis, although in many of these solitary tubercles were present. Hoche (l. c.) with much difficulty was able to stain the bacillus in the pia, arachnoid, etc., in diffuse meningomyelitis.

Usually the nodular spinal tuberculosis presents the picture of acute myelitis. The picture given by Haskovec is as follows: The patient, who already has pulmonary tuberculosis, is seized abruptly with paresthesia, feebleness of the extremities, pain, etc. These symptoms last a certain time with remissions. Some day the patient is suddenly, partially or completely, paralyzed, sensation is altered, vesical and rectal trouble and trophic lesions are observed.

The fact that the tubercle bacillus has not been found in many cases of infiltrating and nodular tuberculosis (Haskovec) suggests the action of a poison upon the cord without the presence of the bacillus.

The effects of tuberculosis may be seen in the entire nervous system; it may not only cause minor forms of degeneration in peripheral nerves which produce no symptoms, but also severe inflammatory and degener-

Ha skovec: Archives de Neurologie, 1895, xxx, p. 177.

31 Hoche: Archiv für Psychiatrie, xix.

ative processes with the symptom-complex of multiple neuritis (Oppenheim³²). Carrière³³ has found neuritis in tuberculous patients when the cord was normal. As he was unable to find the bacillus and to produce tuberculosis in guinea pigs after inoculation with portions of these altered nerves, he concludes that the neuritis was due to the tuberculous poison.

Case No. 4, reported by Schamschin,³⁴ is worthy of special mention. External tuberculous spinal pachymeningitis, with basal tuberculous meningitis was found. The meninges upon the pons were infiltrated with leucocytes. Specific tuberculous lesions—miliary tubercles and giant cells—were not observed microscopically in his sections from the pons, although macroscopically miliary tubercles had been noticed on the brain. Very little mention is made of giant cells within the cord. A slight degree of leucocytic infiltration was observed throughout the cord and its pial membrane. The spinal roots were also invaded by the cells. There were no miliary tubercles found within the cord or its pia, either macroscopically or microscopically. The statement is made that in the region of the pons the perivascular areas were infiltrated with leucocytes.

Hektoen³⁵ has called attention to the vascular changes in tuberculous meningitis. In all nine cases examined by him extensive vascular lesions were noted, and in only one of these was there evidence of mixed infection. In one of Hektoen's cases (No. 7) there were no distinct evidences of giant cells in any of the sections.

The findings in most cases of tuberculous meningitis, as given by Hektoen, are diffuse and circumscribed cell infiltration, with comparatively many giant cells and occasional districts of caseation and also much fibrinous exudate, all of which seems more marked at the base of the brain and in the beginning of the Sylvian fissures.

From the cases which have been quoted it will be seen that the absence of specific lesions in meningomyelitis, or the failure to stain the bacillus does not exclude the possibility of the tuberculous nature of the process. There are cases which seem to be due to meningitis and yet on examination no organic changes are found in the meninges. Some of these may belong to the form described by Quinke³⁶ as meningitis serosa. The French (Dupré) speak of *méninisme*. There are, on the other hand, mild grades of tuberculous meningitis which probably cause no symptoms.

In the case which forms the subject of this paper, tubercles were found in the lungs, spleen and liver, and some of the lymph glands were tuberculous. The brain and cord when examined in the fresh state were found congested.

We can only say with certainty that there was a condition of meningomyelitis of moderate intensity in a patient with disseminated tuberculosis, but we may add that just such a condition as this has been several times reported as tuberculous. It is true that tuberculosis, especially when the lungs and gastrointestinal tract are affected, is liable to be a mixed infection, and there is a possibility that the toxins produced by other micro-organisms than the tubercle bacillus may have called forth this condition of spinal

inflammation. Such micro-organisms, however, are not to be detected within the central nervous system in this case, and we must be content for the present with the statements made by certain writers that tuberculous meningitis may exist when the presence of the bacillus can not be demonstrated in the nervous system.

DISCUSSION.

Dr. JAMES HENDRIE LLOYD—This was a case of mine at the Philadelphia Hospital. It seemed very evident from a clinical study of the case that the man was suffering from some form of blood poisoning. He had not, clinically, the history of a multiple neuritis. He had a very remarkable condition of thickening of the whole vascular system which, considering that he was only 40 years of age, was quite extraordinary. It seemed to indicate that the vascular walls had been subjected to some kind of irritant which set up some form of thickening. We diagnosed tuberculosis, but at the time it did not occur to me as a possibility that tuberculosis could produce that train of symptoms, which in his case seemed largely to be confined to the motor neurones. After Dr. Spiller's study of the segments, however, I came to that conclusion. He had no lesions of syphilis and it remained for us to fall back upon tuberculosis.

Dr. HUGHES—You will recall the distinction that Gowers makes between neural and adneural states as the result of syphilitic infection, and that it is upon this fact in the earlier stages of venereal implication that we found our hope of cure and based our confidence in the possibility of a successful prognosis. Syphilis is an extra-neural or adneural affection.

Dr. PATRICK—Many of the symptoms of meningitis, whether tubercular or of the ordinary cerebral spinal type, or of some other source of infection, are sometimes due largely to something else than the discoverable lesion; that the principal symptoms are due to the systemic affection, or the action of the toxin upon the nervous system and not directly to the inflammation of the meninges.

I have been engaged for a number of months in the microscopic examination of specimens from a case of superior and inferior encephalitis. The patient died after six or eight weeks, from respiratory insufficiency. Macroscopically there was absolutely nothing to be seen; microscopically there was not very much. There is a marked dilatation and injection of all the arterioles of the bulbo-pontine region, also marked dilatation of the smallest arterioles, the largest vessels being very little affected. The nerve cells are almost intact. In many of the nuclei corresponding to the paralyzed areas, it is a question whether the nerve cells are normal or not; as far as the nerve fibers are concerned there are very few places that are even doubtful, and they are nearly all unquestionably normal. This was a case of toxemia of some kind, although no such source was discoverable, which acted upon the coats of the vessels, and which filtrated through and affected the nerve cells and fibers, causing paralysis and death, without any marked changes that are discoverable to the present technic. The case seems to be one that shows the intimate relation between the recognized organic and the functional cases. We know of an asthenic bulbar paralysis, with no findings by the best of men; we know apparently of a toxic disease, Landry's paralysis, sometimes with no findings; and now we know of an encephalitis, with punctate hemorrhages, with evidence of disease of a gross nature. It seems to me functional cases are simply toxemic, though not recognizable as such.

Dr. MOYER—I have recently seen a case which I regarded as a case of Landry's disease. There was an ascending paralysis beginning in the lower extremities; there were three distinct invasions of paralysis; two partial recoveries; and the third attack rapidly advancing to the involvement of the respiratory muscles and death. The whole history of the disease extended over forty days. Unfortunately there was no autopsy. The reflexes were at all times exaggerated to some degree; that is, the knee-jerk and deep reflexes. There was no ankle clonus, however. This case was one that had all the phenomena of an infectious disease; coated tongue, disturbed alimentary tract, in a word, all the phenomena that you would expect to find in an ordinary case of typhoid fever, except that at no time during the progress of the malady was the temperature raised above normal. I could not escape the distinct impression that I was dealing with some unknown infection, and that some ptomain, some poisonous product formed by bacteria, on being absorbed either generally or in a localized way, was poisoning the nervous system of the patient. I have now under observation a child, only about 6 years of age, who presents a typical picture of the patient last described, and the malady

seems to be progressing in exactly the same way. In this child also there is absolutely no increase of temperature.

These nerve cells are simply poisoned by some ptomain, some toxin, and they do not present any structural changes any more than they would with aconite or strychnia poisoning.

Dr. SPILLER—In regard to Dr. Patrick's statement, I would say that one case of asthenic bulbar paralysis has been reported in which lesions were found. Landry's paralysis is probably due to different causes and different lesions.

A CASE OF TRANSVERSE MYELITIS WITH AN UNUSUAL FORM OF DESCENDING DEGENERATION IN THE POSTERIOR COLUMNS.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY JOHN K. MITCHELL, M.D., AND

J. H. WALLACE RHEIN, M.D.

PHILADELPHIA, PA.

The patient was a man aged 65 years, of great mental and physical activity, and in good health with the exception of the illnesses arising during army service and two or three wounds, one of which was received at Antietam, a fragment of shell striking him between the right shoulder blade and the spine. He was seized suddenly with pain in the area of distribution of the seventh intercostal nerves on the right side, about May, 1896. There was very great tenderness upon pressure or touch and extreme sensitiveness to variations of weather. The pain exhibited an extraordinary obstinacy to treatment, so far as could be learned from the patient's statements.

He was treated by the family physician (a homeopath) for intercostal neuralgia without experiencing any relief. The pain continued in varying degrees of severity, but was never absent during the whole spring and summer; it was often so great as to practically incapacitate him, and he was obliged to give up his business and go away in the hope of getting better.

Other physicians saw him in the course of the disease and gave the opinion that he was suffering from intercostal neuralgia.

In September a pain of somewhat less violent character began in the same situation on the left side. The measures taken to relieve it included continuous pressure upon the painful points, which made it worse, and various drugs. He returned home and went to bed. There was no change in the general symptoms, except for a temporary increase or decrease of pain, until the latter part of November. November 30, upon attempting to rise in the morning, he was quite suddenly seized with loss of power in the legs. This loss did not seem absolute, however, as he could move the legs a little while lying in bed. There was no impairment of control of bladder and rectum.

The physician called in consultation (a homeopath) stated that the knee-jerks were decidedly present, and that the patient was able to move his legs a little.

One of us saw him first three days later. He was then lying upon his back quite unable to move and suffering constant acute pain in the intercostal nerves.

There was very slight knee-jerk on both sides, and the plantar jerk was also present, somewhat stronger upon the right than upon the left side; no cremaster reflexes were demonstrable. The bladder and rectal control was unaltered. There was fair localization to touch on both legs. He was beginning to complain of pain at the level of the sacrum, and the sacral

region was quite sensitive. This sensitiveness increased upward over the whole abdominal region until it became hyperesthetic at the level of the intercostal trouble. There was no fever and the lungs and heart appeared perfectly sound to repeated and careful examination, a point of interest in view of the condition found at the autopsy. Upon examining the patient's back an ill-defined resistance on the right side of the column over an area which covered the levels of the fifth, sixth, seventh and eighth dorsal vertebrae was readily made out. This increased resistance was decidedly less marked upon the left side than upon the right. Percussion over the same area gave a slight increase of dulness; the limitations were vague even with careful examination with the phonendoscope. No change in this condition was noticed for several days, but in less than a week the knee-jerk had entirely disappeared and no reinforcement was obtainable. Control of the bladder and rectum was now lost, the urine having to be drawn and the bowels moved by enemata. The patient still complains of pain in the intercostal regions and immediately below, especially if the bowels were not kept freely open. In that event an accumulation of gas would distend the abdominal walls and cause increasing pressure upward with consequent pain. One or two small bed sores appeared, but careful nursing resulted in healing for a time. In spite of care, however, after some weeks a large slough formed upon the sacral region and another upon the left buttock. These were followed by others, and the patient died from exhaustion January 15.

It had been our theory from the first that the trouble was in some indirect way due to the spinal injury received from the shell wound at Antietam, and this opinion was founded upon the observation of several cases previously seen, where spinal wounds which at first seemed to be only moderately severe concussions had many years after (twenty-seven years in one case, twenty-five in another) determined degenerative changes quite sudden in onset.¹

The autopsy furnishes points of great interest. The specimens were stained by various methods to exhibit the several forms of degeneration and a full report of these studies follows:

Autopsy. Twenty-six hours after death. On exposing the column it presented no external deformity. After section the fifth, sixth and seventh dorsal vertebrae were seen to be surrounded with pus. A sac extended on both sides of the column from about the middle of the fifth to the lower margin of the seventh. It burrowed deeply on the ventral side of the column and extended irregularly in a lateral direction, but did not reach the level of the dorsal aspect. The laminae were soft and broke under the saw; all the surrounding tissue, outside as well as inside, was matted and thickened with caseous material, resembling broken down tubercular deposit.

Dissecting the tumor away from the sides of the column, a finger could readily be passed into the posterior mediastinum at this level. The tumor had distinct outline but was not sacculated. The laminae and spinous processes were all involved and much necrosed and disorganized. The fifth and sixth vertebrae were especially broken down, the spines less than the bodies. The posterior roots of the eighth pair of

¹ Several of these cases are fully reported in a small volume by Dr. J. K. Mitchell, on "Remote Consequences of Injuries of Nerves." Lea Bros., Phila., 1893.

nerves were much enlarged and thickened at their exit from the column, the sheath being especially indurated, and measuring one-quarter centimeter in diameter. The rib articulations to the fifth, sixth and seventh vertebrae were necrosed. It was necessary to separate the dura, by dissection, from the caseous mass of which it seemed to form a part, and even above the level of the tumor it was decidedly adherent. The vertebral destruction was much more marked on the right side than on the left.

Upon opening the cord the dura was found thick and tough, in many places more than one centimeter in thickness. In the region of the tumor the cord was flattened laterally. It was dotted with a creamy semi-fluid material in spots and so broken down that it could not be cut.

There was no other marked macroscopic change, except that the cord seemed to be gray in color. There were a few small tumors scattered throughout the lungs and many of the posterior mediastinal glands were enlarged. The other organs presented no abnormality. The appearance was very much like that of tubercular disease of the bone with exudation around the focus of the disease; but sections from the spinal tumors proved it to be a sarcomatous growth. The tumors in the lungs were evidently the result of metastasis.

The spinal cord was placed in Müller's fluid. The cord was so soft and disintegrated at the level of softening that it was not possible to make any sections from this part. This softening extended a distance of five to six centimeters. Sections were made immediately above and below the softened area and from other levels above and below and stained by the Weigert-Pal method, by carmine and by the Marchi method. The dura mater was irregularly thickened about the softened portion varying in thickness in the crossed section from one to nine millimeters. The cord was not greatly narrowed, but was somewhat flattened. In a recent state it was soft and pulpy.

Microscopic examination (Weigert-Pal method) gave evidence of extensive degeneration in the posterior columns immediately above the softening, involving the columns of Goll more intensely than those of Burdach. With the exception of a narrow band adjoining the posterior horns, the whole extent of the latter columns was involved. The direct cerebellar tracts were moderately involved. Gowers' columns were quite markedly degenerated, the direct and crossed pyramidal tracts remaining practically free. Above this in the lower cervical region the posterior columns were intensely involved, more especially the columns of Goll. Quite a distinct line could be observed between Burdach's and Goll's columns, but the former were also affected, though less severely. There remained many well stained fibres adjoining the posterior roots. The pyramidal tracts were exempt. On both sides the direct cerebellar tracts were involved to a moderate degree, and Gowers' column quite markedly, except at that portion adjoining the crossed pyramidal tracts. Farther up in the cervical region the degeneration was localized in the posterior columns, almost entirely to the postero-median columns, the line between these and the healthy postero-external columns being quite distinct. Gowers' and the direct cerebellar tracts were more intensely degenerated.

In the dorsal region a short distance below the softening, there was a moderate amount of degeneration in the postero-median columns at their anterior sec-

ond and third fifths and this extended over on one side as far as the anterior horn and was quite marked; on the other side the process was slighter in degree. In the crossed pyramidal tracts there was a moderate degree of degeneration on both sides, extending well forward and also in the anterior pyramidal tracts. Lissauer's tracts on both sides were moderately involved. The posterior and the anterior roots were both degenerated at this level.

In the lumbar cord in the upper levels the posterior tracts were apparently exempt. The crossed pyramidal tracts were moderately degenerated, and the posterior root zones were involved.

In the lower lumbar cord the lateral columns were still affected, the remaining portions of the cord staining well everywhere.

In the sacral cord the descending degeneration was still traceable in the lateral columns.

In the cervical region the anterior roots showed increase of the connective tissue, and degeneration of the nerve fibres, though this was not extensive. The same thing may be said of the posterior roots below the softening in the lower thoracic cord and also, to a much less extent, of the anterior roots. In the lumbar region the posterior roots were markedly affected, the anterior remaining practically free.

Showing Schultz's tract; 9th thoracic.

Upper lumbar.

Sacral.

Showing descending degeneration in posterior columns.

Microscopic examination by the Marchi method showed recent degeneration. Above the softening the whole extent of the cord showed recent changes but especially in the columns of Goll, Gower's columns, and the direct cerebellar tracts, where they were very intense. Higher up the degeneration was less marked, but still present everywhere. Around the periphery of the cord and in the posterior columns it was still quite extensive. Below the softening the acute degeneration invaded the entire cross section of the cord with the exception of a small focus behind the crossed pyramidal tracts. The degeneration was profuse throughout the posterior columns save centrally where the middle two-fifths seemed practically exempt. The anterior and posterior roots shared in this acute inflammation and the reflex collaterals were also involved. In the antero-lateral tract between the direct pyramidal and direct cerebellar tracts there was slight degeneration in an area corresponding to the descending antero-lateral tracts of Foster.

In the dorsal region further down there was slight degeneration on either side situated behind the knee of the posterior horns. Throughout the whole tract, however, there was a slight diffuse degeneration; and

on one side this was more intense in the area corresponding to the comma shaped tract of Schultze. This was about the ninth thoracic segment. In the upper lumbar region this had disappeared. A slight degeneration was seen, limited to that part of the postero-median column adjoining the posterior median fissure, more intense at the periphery, disappearing about half way between the periphery and the posterior commissure. Clarke's columns were not involved.

In the sacral cord the same degeneration was observed in the portion of the posterior column bordering on the posterior fissure. It was club shaped and extended slightly farther forward than in the upper level.

Carminic stain.—The carminic section showed much increase in the connective tissue in the posterior tracts. The nerve fibers had undergone extensive degeneration, were fused into masses and had lost all resemblance to their original appearance. There were numerous blood vessels with thickened walls, some were obliterated, the walls of others crowded with nuclei. This change existed, though to a less extent, in the lateral, and still less in the anterior tracts. In the gray matter there was intense change and the ganglion cells were profoundly degenerated. The angles were rounded, the prolongations lost in many; others showed granular change and appeared globular in form, containing elongated nuclei. There were numerous capillaries and small vessels and an extreme degree of round-celled infiltration existed. Occasionally a ganglion cell was found in fair condition, but this was rare. In the cervical region higher up, a similar change was observed. Hemorrhages into the gray matter were present, but the ganglion cells were less extensively involved, in many the prolongations persisting. There were numerous capillaries choked with red blood cells. The axis cylinders in the anterior roots were swollen in many places and some had disappeared. In the posterior roots there was an increase in the connective tissue and many swollen axis cylinders were present.

Immediately below the softening the condition was similar to that described, as existing immediately above it. The whole transverse area was degenerated in a diffuse manner. In the upper lumbar level the change in the gray matter was very much less extensive, most of the ganglion cells retaining their normal characteristics. In the sacral region the gray matter was the seat of slight inflammatory change. A number of capillaries filled with blood cells were seen and also a considerable amount of round-celled infiltration. A number of ganglion cells were rounded, but most of them retained their prolongations.

In this case the usual ascending and descending degenerations following a transverse lesion of the cord were present. The ascending degeneration involved the posterior columns, especially Goll's tracts, the cerebellar tracts and Gowers' columns. Below the lesion the pyramidal tracts were degenerated along the entire extent of the cord. There were a few fibers between the anterior lateral tracts which were diseased, corresponding probably to those described by Foster as the "descending antero-lateral tracts." In the posterior columns in the lower dorsal region was a wedge-shaped area of degeneration situated in the postero-external tracts just behind the knee of the posterior horns on one side, spreading faintly into a comma-shaped area corresponding in position to that described by

Schultze. In the lumbar and sacral regions this was not present, but a small area of degeneration was seen adjoining the posterior fissure on each side at the peripheral half and taking the shape of a club in the sacral region.

This descending degeneration in the posterior columns is exceedingly interesting, corresponding in many respects with that already described by a small number of observers. The descending degeneration in the posterior columns which occurs in the cervical and upper dorsal regions was described first by Schultze² in 1883, who called it the "comma-shaped column." But Bastian³ in 1867, Kahler⁴ and Pick, and Strümpell⁵ in 1880, had already described a descending degeneration in the posterior columns. This tract has since been described by Westphal,⁶ Tooth,⁷ Schmaus,⁸ Brunn,⁹ Pfeiffer¹⁰ and Daxenberger.¹¹ According to Obersteiner this tract is seen when the cervical cord is destroyed and does not extend below the upper dorsal region. Daxenberger claims that it descends the entire length of the cord; but in Strümpell's case it did not reach below the seventh dorsal nerve; in Schultze's case not below the middle dorsal, and in Tooth's case it was not found below the eighth dorsal segment. Dexler¹² found the column (Schultze's) in the spinal cord of a dog which was compressed at the lumbar swelling. Bischoff,¹⁴ in a case of compression of the cord in the upper thoracic region, described the comma-shaped tract in the posterior columns which did not extend below the eighth thoracic segment. Below this there was a diffuse degeneration about the middle of the postero-median septum. In the lumbar region the fibers were brought together and collected against the dorso-median border. This diffuse degeneration extended from the eighth thoracic segment to the sacral region.

In our case there was seen what was probably the terminal portion of this tract at the lower dorsal segment. Beginning a short distance below this was a second tract of descending degeneration, limited to that part of the posterior median tracts adjoining the posterior median fissure and extended from the periphery to half way between this and the posterior commissure. It occurred in the lumbar and sacral regions only. In the sacral region it was more marked and became club shaped. This tract has been described only by a few observers. Obersteiner mentions it in his "Nervösen Centralorgane." He states that it begins in the lumbar region as a small strip bordering on the posterior septum and takes the shape of a club in the sacral region, where it is particularly marked. It finally appears as a three-sided area along side the median line and corresponds to the oval field of Flechsig. Obersteiner calls it the "dorso-median sacral bundle." Tooth does not mention this tract in his Gulstonian lectures, delivered in 1889, though he refers to Schultze's tract, and it has also escaped description in Quain's "Anatomy." In a case recently reported by Bruce¹⁵ and Muir, in

which there was an injury to the cord at the tenth dorsal vertebra, a descending tract was found very similar to that described in our case. The degeneration was irregularly spread throughout the greater part of the posterior columns in the upper lumbar region. It then became located in the vicinity of the postero-median septum and the periphery of the inner half of the posterior commissure and finally took the form of a wedge with its base toward the periphery and apex toward the commissure. Its fibers terminated in the gray matter at the base of the posterior horns on the same side. It seemed to Bruce and Muir that this tract was independent of Schnltze's comma-tract and also of the cornu-commissural tract of Marie. They believed it to correspond to Flechsig's "oval field" and Obersteiner's "dorso-median sacral bundles." They call this the "descending septo-marginal tract," which seems a very appropriate name.

In the case reported by Déjerine and Spiller¹⁶ in which there was a lesion of the cauda, an ascending degeneration was observed occupying the whole posterior column with the exception of the oval field of Flechsig; this could not be found above the first lumbar segment. It has been claimed that Schultze's tract is composed of the descending fibers of the posterior roots, but in a case reported by Tooth in which the fifth thoracic nerve was degenerated this tract was not present.

The absence of knee-jerks one week after the onset of spinal symptoms is interesting in relation to the question raised by Bastian,¹⁷ who first called attention in 1882, to this association of absence of the knee-jerks with total destruction of the cord (Quain's Dictionary). The statement was viewed with a great deal of skepticism on the part of many observers and has not yet been universally accepted. Again, in 1890¹⁸ he reported cases illustrating this condition and also referred to cases of Tooth, Kahler and Pick, and Thorburn, in which the reflexes were lost in transverse lesion of the cord due to fracture dislocation. On the contrary, Gowers claims that reflex action is excessive except when the disease involves the lumbar enlargement.

Bischoff (*Wien. Klin. Woch.*, October, 1896), in a review of the literature of the subject collected thirty-one cases. He concluded that the reflexes are either lost from the beginning, or first increased and later lost in a certain percentage of cases. The reflexes were increased in two cases of complete destruction of the cord. An autopsy was made in only one of these cases in which the ganglion cells and crossed pyramidal columns were found diseased. In three cases of incomplete destruction, the reflexes were not lost. There was no autopsy in these cases. The author concludes that the reflexes may be lost when the lesion has not been complete, or may be present when the lesion has been total. He believes that the lessened reflexes are due to a condition independent of the spinal lesion, its completeness or its height, and of the ensuing degeneration. He holds that there is a paralysis of the vasomotor nerves supplying the abdominal viscera and the lower portions of the body and also of the motor and sensory fibers, causing dilatation of the vessels in these parts, and lowering of the general blood pressure. The anemia thus pro-

duced lowers the vitality in the lumbar region and hence the tendon reflexes are lost. On the other hand, Habel (*Archiv f. Psychiatrie*, 1897) reports thirty-one cases of which three were examined microscopically; in eight the reflexes were lost. He concludes that the tendon reflexes are lost when there is compression or total destruction of the cord, in the cervical and upper thoracic regions. He claims there is not constant loss of skin reflexes. The tendon reflexes in the case reported in this paper were lost and there was also degeneration of the gray matter and of the posterior root zones in the lumbar cord. Brunn (*Archiv Psychiatrie Nervenh.*, No. 25) reports a case of complete traumatic destruction of the spinal cord in the lower cervical and upper dorsal region in which the knee-jerks were lost. It is evidently essential to the decision of this question that a number of cases should be studied accurately, clinically as well as histologically. It is alike impossible to determine without an autopsy of any case of fracture, dislocation or compression myelitis, whether the lesion is limited to one spot, or to determine the amount of secondary degeneration which may follow destructive lesions.

NEURASTHENIA ESSENTIALIS AND NEURASTHENIA SYMPTOMATICA.

Presented in the Section on Neurology and Medical Jurisprudence, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY F. X. DERCUM, M.D.

CLINICAL PROFESSOR OF NERVOUS DISEASES, JEFFERSON MEDICAL COLLEGE;
NEUROLOGIST TO THE PHILADELPHIA HOSPITAL.
PHILADELPHIA, PA.

At the present day there exist, not only in the mind of the general practitioner, but even in that of the specialist, the most vague and ill defined notions concerning neurasthenia. Not only do we hear from physicians of the highest standing allusions made and views expressed in regard to neurasthenia which disclose that this all important affection has never received serious study or attention by them, but this is true to a very large extent of neurologists and especially alienists. A striking illustration of this proposition is furnished by the treatise on the pathology and therapy of neurasthenia, by Binswanger, which has recently made its appearance in Germany. This writer does not hesitate to say that under neurasthenia we are to group all neuropathic appearances which rest on a basis of a general functional disease of the nervous system but which can not be placed in the same category with the fully developed psychoses and neuroses because of their incomplete character. Surely the pages of medical literature have never before proposed, as the definition of a well defined and well known syndrome, such as neurasthenia certainly is, terms more vague or more unsatisfactory. It is largely because neurasthenia, to the superficial observer, seems uninteresting, that it is so little studied, and yet it is an affection so common, the number of cases so large, that we certainly owe it to ourselves to obtain clear, if not elementary, notions of this disease. In truth, neurasthenia is one of the most interesting affections which we can possibly study. As I will point out, its syndrome is as definite and fixed as that of any other disease with which we have to deal. Its boundaries instead of being illy defined are sharply delimited. The various symptom-groups occurring in neurasthenia, though differing widely in detail, always present

¹⁶ Déjerine and Spiller: *Comptes Rendus d. l. Soc. d. Biologie*, 1895, p. 27.

¹⁸ Bastian: *Medico-Chirurgical Transactions*, London, 1890, Vol. 73.

the same essential features and, from whatever standpoint they are approached, a harmonious clinical whole—a well proportioned and well defined syndrome—is seen. The work of Binswanger illustrates in reality a backward step. If it is to stand, the writings of Beard, Bouveret, von Hösling and others to whose labors we owe, in a large measure, our present notions of the disease, fall to the ground, and all the value of the pioneer treatise of Robert Whyte, now over a century and a quarter old, which differentiates this affection clearly from the allied conditions of hysteria and hypochondriasis, not to speak of the writings of Sandras, Bouchut and others, disappears.

Let us analyze briefly the essential features of neurasthenia. In the simplest form of the affection there exists a more or less marked and persistent diminution of nervous energy, and to these symptoms are added those of increased irritability both mental and physical. It does not seem that much mystery should attach to this condition; it hardly seems necessary to contend that marked chronic fatigue should present a special syndrome, and yet Binswanger would have us believe that we are dealing with a condition which presents the most vague and indefinite symptomatology. These vague notions of neurasthenia are based upon incomplete study and upon the apparent inability to systematically arrange and properly classify the facts presented. Neurasthenia is still in the position in which hysteria was until recent years in England and America, notwithstanding the French had demonstrated unmistakably the symptomatology of the latter affection. Too often neurasthenia is looked upon as a vague affection made up of numerous pathologic factors bearing little or no relation to each other. The difficulty partly arises from the fact that the symptoms of neurasthenia are in a large measure subjective, while even such symptoms as are objective lack the striking features observed in many other functional diseases. Another circumstance which has been most prolific of misconception regarding the nature of neurasthenia is that physicians have loosely described as neurasthenia symptoms which properly belong to other diseases. Thus the nervous symptoms associated with anemia, chlorosis and other diseases of the blood, the nervous symptoms associated with the diseases of the pelvic organs or with chronic diseases of the stomach, have been loosely termed neurasthenia. If the nervous symptoms associated with general somatic or organic diseases are to be termed neurasthenic, we should be careful to bear in mind that they represent something very different from true neurasthenia. I have proposed for this spurious neurasthenia the term neurasthenia symptomatologica. If the fact that there exists a true neurasthenia separate and apart from symptomatic neurasthenia, is once firmly fixed in our minds, much of the confusion clinging to the subject passes away.

The next fact of importance to recognize is that in true neurasthenia, or as I prefer to term it, neurasthenia simplex or essentialis, in addition to symptoms primarily indicative of the disease, others make their appearance which are secondary in character and importance. Frequently these secondary or subsidiary symptoms are superficially evident or unusually prominent, and thus their importance is mistaken and overrated. Charcot also recognized these differences in the symptoms of neurasthenia, for he separated the symptoms into cardinal symptoms or neurasthenic stigmata and accessory symptoms. In Charcot's group

the fundamental symptoms or stigmata are the following: 1, neurasthenic headache; 2, sleep disturbance; 3, rachialgia and spinal hyperesthesia; 4, muscular weakness; 5, the disturbances of digestion (nervous dyspepsia); 6, sexual disturbances; 7, mental symptoms. To these Charcot added the secondary or accessory symptoms, which group consists of all those not essential to the diagnosis of neurasthenia. Among them he placed such symptoms as giddiness, disturbances of the special senses, respiratory, circulatory and secretory, disturbances of general sensation, of motility and febrile conditions.

Charcot in his classification of the symptoms of neurasthenia merely grouped together as the stigmata, or fundamental symptoms, the most prominent clinical features of the disease. We will find by analysis that these symptoms are not of equal value, and this is also true of the secondary symptoms just enumerated.

If we grasp the conception of neurasthenia, that it is in reality a fatigue neurosis, the symptoms group themselves very readily in a logical and orderly sequence. Primary or fundamental symptoms then stand out boldly and with definite relations to each other. They are always symptoms which present the characteristics of weakness and irritability and which are always expressive of fatigue. The secondary symptoms are all such as are adventitious or mere secondary outgrowths of the primary. I can make my meaning clear by enumerating some of the various primary and contrasting them with some of the secondary symptoms. Beginning with the sensory disturbances we have, first, a general sense of fatigue. This sensation may be diffused throughout the entire body, but it is generally accentuated in special regions or limbs. It is characteristic of this sense of fatigue, whether it be referred to the head, to the back or limbs, that it is, in the simple and typical cases at least, always relieved or lessened by rest, and further, it is always brought on if absent, or made worse if present, by exertion. This readiness and general sense of fatigue I regard as the primary symptom, if indeed not the most fundamental of all the symptoms, of neurasthenia. Fatigue sensations when exaggerated become painful and are then described by the patient as aches of various kinds. It is frequently a headache, almost as frequently a backache, or the ache may be referred to a leg or to an arm. In the latter instance a few questions with reference to the avocation will almost always reveal the reason for the accentuation of the pain in one extremity. Thus, in a collector, the fatigue sensations were most pronounced in the legs; in a physician who used his right hand constantly and for many hours daily in laryngeal manipulations, the fatigue sensation was accentuated in the right arm.

These aches of various kinds are primary symptoms. Not infrequently, however, we have associated with these symptoms others which are secondary and which I have termed adventitious. Thus, the headache of neurasthenia may be accompanied by a sense of pressure or constriction or of fullness, lightness or distension. These sensations, depending as they probably do, upon disturbances of the circulation, are secondary and adventitious. They are not necessary parts of the neurasthenic headache and may or may not be present. Sometimes other sensations are noted, such as throbbing, sense of increased weight, whirling sensations, or vague and ill defined feelings of distress; all of these are secondary in value.

As regards backache, the simple feeling of fatigue referred to the lumbar region may be complicated by hyperesthesia, especially over the spinal gutter, where it may be distributed in patches; I refer to so-called spinal hyperesthesia or spinal tenderness. This I regard as a secondary symptom. It is a pathologic exaggeration or intensification of the fatigue sensation. The hyperesthesia, the sense of burning and the deep-seated boring pains sometimes complained of, are clearly adventitious and not primary. The aching referred to the legs or arms, present a similar illustration. It is very frequently found that in addition to, or in place of aching in the limbs the patient complains of throbbing and tremulous feelings. They are not necessarily present and are clearly adventitious. The various curious paresthesiæ of which neurasthenics complain, such as numbness, prickling, or of velvety sensations, all belong to the group of secondary symptoms.

If we analyze the various visual disturbances of neurasthenia we find that the same truth is evident. Here the principal symptoms are those expressive of fatigue. I will not analyze them in detail, but allude briefly to a few of them. One of the most common statements made by neurasthenics is that they are not able to read for more than a few minutes at a time, and if they persist, the letters become blurred and indistinct and the effort gives rise to pain, generally headache. It is probable that in this symptom there is involved a three-fold weakness of retina, muscular apparatus and cerebral centers. Irritability is noticed in the fact that many neurasthenics are unable to withstand any but the slightest exposure to light on account of the painful sensations produced. It is for this reason that so many neurasthenic subjects spontaneously begin the use of smoked glasses. Ready fatigue and irritability are primary symptoms; others are frequently present; thus, patients will declare that everything appears as though seen through a mist or veil, or that objects look exceedingly dull or unusually bright, or as though they were far away or at times excessively large. All of these symptoms are secondary in value; they are all adventitious to the primary symptom, visual fatigue.

The same difference also obtains with regard to the disorders of hearing. Slight impairment of hearing coupled with auditory hyperesthesia, great irritability to sounds, obtain in a very large number of cases, and these symptoms are primary and fundamental. In addition, paresthesiæ are frequently complained of. They consist of various forms of tinnitus, such as roaring, buzzing, whistling sounds and at other times of throbbing, beating or tickling sensations. These are beyond doubt adventitious and bear but a secondary relation to the fatigued condition of the auditory apparatus. I might point out similar disorders presented by the senses of smell and taste. I need only briefly allude to the excessive sensitiveness of some neurasthenic patients to odors and also to the fact that olfactory paresthesiæ sometimes occur. This is equally true of the sense of taste. The accuracy of the latter is often distinctly lessened and very frequently paresthesiæ are present, so that common articles of food present strange and often disgusting flavors.

When we turn to the motor phenomena we find that these also resolve themselves into primary and adventitious symptoms. Muscular weakness is so pronounced a symptom of the average case of neurasthenia

that it was constituted by Charcot one of his fundamental symptoms or stigmata and termed by him *amyosthenia*. This is a primary symptom, and yet it is frequently associated with other symptoms, such as tremor, which may present itself in a characteristic manner as a fine intention tremor of the hands or it may be limited to certain groups of muscles or even to a few fibers of a muscle. When present as an intention tremor it is most readily demonstrated in the extended hands. When limited to special bundles of fibers it is most frequently observed in the muscles of expression, notably in recurring twitchings of the orbicularis palpebrarum or of a few fibers of the frontalis or the orbicularis oris. These intention and fibrillary tremors are evidently not primary but adventitious and secondary. The term primary should be restricted to the amyosthenia itself.

When we turn to the disturbances of digestion, of circulation, of secretion and of the sexual functions, the same general truth is noted. Regarding digestion, the primary symptom is that of digestion enfeebled and delayed, *i. e.*, atonic indigestion—an indigestion also associated with an atonic constipation. The secondary symptoms that sooner or later make their appearance are those of a gastric catarrh, the result of abnormal fermentation accompanied by the formation of abnormal acids. Evidently gastric catarrh with its abnormal acidity, excessive or diminished, is a secondary or adventitious condition. The disturbances of the circulation afford another illustration. The coldness of the extremities, the feebleness of the pulse, are primary symptoms and expressive of general weakness. The disturbances in the rhythm as manifested by irregular action of the heart or of cardiac palpitation, are to be regarded as adventitious symptoms. The circulatory apparatus, together with the nervous mechanism controlling it, is in a condition of irritable weakness and that, as secondary outgrowths of this irritable weakness, there should be gross disturbances of its rhythmic action, is not surprising, but these disturbances must be looked upon as secondary and not essential to the clinical picture of neurasthenia. The disorders of rhythm may be so great as to mount to most frightful attacks of tachycardia. The various heart murmurs that are occasionally noted in neurasthenic subjects are likewise to be relegated to the secondary group, as are also the loss of vasomotor tonus, as made evident by involuntary flushings of the face or other portions of the body, or on the other hand by such symptoms as aortic pulsation.

The sexual disturbances also reveal as primary symptoms, weakness and irritability, and in addition, as secondary symptoms, various paresthesiæ, such as pricking, creeping, throbbing or cold sensations. The secondary symptoms are indirect outgrowths of the primary weakness and irritability.

The psychic symptoms of neurasthenia can be isolated with the greatest readiness. The first symptom that we note is the diminution in the capacity for study or intellectual effort. To attempt to do mental work, sooner or later brings on in the neurasthenic symptoms of exhaustion. If the task be persisted in the fatigue sensations become very pronounced and in addition to headache secondary symptoms, such as sensations of constriction, giddiness and even vertigo, make their appearance.

The next symptom is also one indicative of weakness. It consists in a lack of the power of concen-

trating the attention, and this the patient frequently mistakes for loss of memory. Other symptoms of weakness are lack of spontaneity of thought, a diminution in the strength and emotional irritability. These symptoms are all referable to the primary group. In a large number of patients, however, other symptoms make their appearance, which are clearly secondary in character; associated with the general incapacity for exertion, the weakness of concentration and lack of spontaneity, there is often an apparently causeless, general sense of fear. This may be vague and ill defined and consist merely of a general feeling of anxiety. More frequently, however, it takes some definite form. The patient experiences a sudden sense of fear which is uncomplicated and may be slight or so intense as to be horrible and overwhelming, or instead, we may have the special fears which have been described by various writers, notably by Beard. They find an apt illustration in the fear which a perfectly healthy person experiences when standing at a great height, even though they know themselves to be in a perfectly secure position. In neurasthenics these special fears assume the most aberrant forms. It is hardly necessary in this connection to refer to agoraphobia, claustrophobia and their congeners. Let it suffice to say that all the forms of fear, from the simple and purely generalized to the most highly specialized, all belong to the secondary group of symptoms. For some reason Charcot placed the various special forms of fear presented by neurasthenics in a third group of symptoms, but certainly, if we regard neurasthenia as a fatigue neurosis with secondary outgrowths and complications, this formation of a third group of special mental phenomena is not justified.

Neurasthenia is not a vague and ill-defined affection, as Binswanger would have us believe. I contend that it is an affection with a syndrome as well defined and established, as any with which we have to deal. The moment we regard neurasthenia in its true light, that of a fatigue neurosis, much of the mystery passes away and the essential symptoms, those directly expressive of fatigue, stand out prominently and give to the disease its clinical features. The failure to assign to the secondary symptoms their proper value has been a prolific source of error. Often these secondary symptoms are quite prominent but they should not throw us off our guard. If the case be one of neurasthenia some of the primary symptoms can always be found.

If time permitted I would invite your attention to the pathology of true neurasthenia, to the studies of Hodge with regard to the changes which nerve cells undergo during fatigue and also to the histo-chemistry of neurasthenia—upon the probable source of the uric acid which is so often found in excess and to point out how these factors enable us to draw still more clearly the differences between true neurasthenia and neurasthenia symptomatica. Finally permit me to allude to a condition which I have called "neurasthenia terminalis." It is well known that prolonged and persistent derangement of function may be followed by actual tissue changes. Thus a heart which is constantly overacting, the result of repeated and violent attacks of palpitation, may undergo hypertrophy, or the walls of the blood vessels may become thickened and if the case persists sufficiently long and be associated with deranged tissue metabolism, even atheromatous changes may take place in the vessels; or, if digestive disturbances persist sufficiently

long, secondary terminal organic changes may occur in the digestive tract. That organic changes may also occur in other structures such as the muscles and even the bones, there can be little doubt. These changes are often suggestive of premature senescence. When any of these changes are present in a marked degree the case is classed by us, clinically, according to the diseased condition which predominates. In other words, simple and uncomplicated neurasthenia, if it persists long enough, results in actual tissue changes. and if the patient presents himself before these changes are accentuated in any one organ and they are slight and generalized the case should still be considered as neurasthenic, but be regarded as the terminal form. These are the cases which are largely intractable to treatment.

My object in this paper was merely to present in as condensed a way as possible my own interpretation of the symptomatology of neurasthenia and was prompted especially by the publication of Binswanger's untenable and retrogressive views. I intended to point out the difference between true and spurious or symptomatic neurasthenia and also to give to neurasthenia its proper position in our nosology as a fatigue neurosis.

DISCUSSION.

Dr. THAYER—I had a patient suffering from headache and general prostration. She consulted various prominent neurologists and one pronounced it nervous prostration, another thought it was neurasthenia and another called it hysteria. These affections have symptoms in common, but neurasthenia must certainly rest upon definite symptoms and definite pathologic conditions of its own and must not be confused with hysteria or chorea or anemia.

Dr. CANFIELD—I think that when a physician has to deal with a neurasthenia of considerable duration he is often called upon to treat what has developed later as hysteria, and perhaps the reverse might be true. In some cases it is immaterial whether you diagnose it as hysteria or nervous prostration, so far as the treatment is concerned at the time. The "tired feeling" is the absolute criterion of neurasthenia.

Dr. LICHTY—From particular study of the secretions and of the blood in so-called neurasthenia, I have discovered that perhaps 50 per cent. of the patients suffering from this disease would be more properly classified as anemics or lithemics. When we go further into the study of neurasthenia we will reduce the number of neurasthenic patients and place them in the right category, neurasthenia essentialis being a clearly defined disease.

Dr. BELL—These cases suffer more or less from anemia in some form, and also from derangement of digestion, either stomachic or intestinal, and in order to locate the trouble it is absolutely necessary to interrogate every organ. There are cases in which the digestive difficulty is not present. I was under the impression that Dr. Vandusen of Kalamazoo was the first to describe this disease. The uric acid diathesis and the formation of chlorides are prominent factors in this disease.

Dr. MARGARET A. CLEAVES—I have found that careful attention to the matter of diet and the proper mental and moral care of these patients is of paramount importance. I have used for a number of years, with very great advantage, a combination of electric treatment with rest cure. I have known two cases of neurasthenia to go to the extent of exhaustion of the motor center so that for a long time it was impossible for the patient to stand or walk. There is no doubt that the factor of worry and anxiety has much to do with the production of the true neurasthenic state. In neurasthenia essentialis, due to exhaustion of the brain, I believe strychnia to be the worst drug that can be used.

Dr. HUGH T. PATRICK—I have come to the positive conclusion that there are at least two distinct groups of neurasthenics. The one is in every particular a fatigue neurosis—a nervous exhaustion produced by overtaxing the brain (not the spinal cord). Patients of the other class present almost exactly the same symptoms, but they arrive at the same goal by a different route, by the action of an inadequate cause. For instance, a laboring man overlifts and then develops, one by one, the cardinal symptoms of neurasthenia, by the action of sub-conscious conceptions in his cerebrum. Possibly the rest cure will benefit this man, but if it does it will only be because of its effect upon his mental state. Most of these patients

need not the rest cure, but education, occupation and gradually increased exercise, mental and physical. The business man, on constant strain, who after many years, breaks down, is a distinct type, as opposed to a nervous individual, always dominated by an idea, who receives a shock and from the effect of that develops the neurasthenic state. These two classes are certainly distinct and they should have different treatment.

Dr. WM. G. SPILLER—Neurasthenia may sometimes prove fatal; I have several times seen patients at the point of danger; I think the explanation of nerve exhaustion is applicable to such a condition and I would like to see the nervous system of such a patient examined by the method of Nissl. Within the nerve cells would be found, I think, some change of the chromophilic elements.

Dr. MOYER—My conception of neurasthenia is that of nerve fatigue; if that is not present the condition is not true neurasthenia.

Dr. JONES—The base of neurasthenia is cell-fatigue, and it makes no difference whether in a working man or a society woman. If the nerve cell is in a fairly stable condition, the patient has the neurasthenia described by Dr. Dercum; if he has an unstable nervous system, he has the form described by Dr. Patrick. The real question is as to the stability or instability of the nerve cell.

The complete exhaustion of a center seems to me rather common, although it has been looked upon, perhaps, as other than neurasthenic; but it can be very reasonably explained by the theory of absolute cell exhaustion, the cell being restored under certain conditions and the motor function returning.

Dr. LODER—There are two forms of neurasthenia as widely dissociated as any two diseases of the nervous system. I have yet to see one case of neurasthenia that did not show a very profound hereditary impress. I believe if we put the chromophilic gland under the microscope we will be able to differentiate these cases.

Dr. AUGUSTUS A. ESHNER—Neurasthenia has varied causes. The susceptibility of the individual nerve cell must vary in the same individual under different circumstances. So, too, the designation of "cell tire" must be accepted as exceedingly vague. Perhaps we do not improve upon such a designation if we assume that from excessive or deranged function there result certain metabolic changes, certain alterations in cellular nutrition, which is the essential basis of these varying kinds of neurasthenia or of neurasthenia depending upon a variety of causes. This intoxication, in consequence of the obverse intracellular innutrition, may produce such alterations in neuronic, in ultimate cellular elements, as to give rise to these symptoms which we designate neurasthenia.

While many cases are susceptible to a general line of treatment, the basis of which consists in the re-establishment of internal equilibrium, and into which enter especially the elements of rest, over-feeding and the removal of general psychic disturbances, still the results of therapeutics seem to sustain the view that neurasthenia is dependent upon varied intoxications of the ultimate cellular elements, sometimes cerebral, sometimes spinal, sometimes cerebro-spinal.

Dr. W. J. HERDMAN—For ten years I have been studying neurasthenics with regard to their temperature. I have found it invariably abnormal; almost uniformly raised, but occasionally lowered. As elevations of temperature are known to cause deviations from the normal state of metabolism, this may become, finally, an etiologic factor. Fear is present in some cases as one of the sequelæ of neurasthenia. One patient who had recovered from this disease, suffered from a horror of elevation. It was impossible to make him go higher than the second story of a house. When in elevators it was necessary to restrain his mad impulse to try to jump out.

Dr. CLEAVES—I have found that this sequel of fear has been relieved by Franklinization.

Dr. DERCEM—Neurasthenia is a fatigue neurosis, and all that is not a fatigue neurosis is something else. Possibly it may be an obscure case of interstitial nephritis, in which it is necessary to make repeated search in the urine to find the proof; and you have other cases of pseudo-neurasthenia: the mere fact that they reveal some of the symptoms, though not the true syndrome, does not make them neurasthenia. There are certain persons who are born with a certain predisposition, and under certain strains become neurasthenic; these are the patients who become insane if the strain is prolonged, and who may become paranoiacs in later life.

It is possible to have neurasthenia from physical exertion. A fatal case of neurasthenia was of a college athlete who had overtrained. He broke down and became profoundly neurasthenic. It was a purely physical case; he did not study hard at college, but exercised very severely. He became a terminal

neurasthenic, and grew to be like an old man. I could not get an autopsy, but as far as I could tell there was no disease of any one organ.

I have observed slight variations of temperature. It sometimes rises as a result of animal fatigue, and perhaps we have here a hint as to the temperature of neurasthenics being slightly above normal. I believe that fears are a secondary outgrowth. They belong to the secondary symptoms, and I suspect that in those cases in which they are so tenacious, and become a part of the individual, there is some neuropathic strain.

With respect to the pathology of neurasthenia, it seems to me very unfortunate that we have not paid more attention to the remarkable results of Hodge's experiments on the fatigue of nerve cells. Hodge first studied bees from the same hive. Several were penned in the hive; others were on their flight all day carrying honey. He killed one of each at the same hour, took the same ganglion from each and compared them. He always found that the cell from the bee that worked was smaller, and there was a tendency to vacuolation of the general cell contents, while the nucleus stained differently. He tried similar experiments with pigeons, and the cells showed the same changes. He excised the posterior spinal ganglia in cats. To exclude all possible sources of error he would take the same ganglion on the two sides, exciting one by the electric current. There were marked changes in cell substance.

The urine is never normal, and there is always some derangement as regards the uric acid. The excessive nuclear waste would account for the increase of uric acid in these cases.

The protonucleins stimulate these cases, but the amount of good has never been enough to make it an essential part of the treatment. It is probable that such benefit as has been obtained from the Brown-Séquard injections is due to the fact that the elixir contains a very large amount of the protonuclein in its active form.

I have come to the conclusion that strychnia increases the nervousness. I use it only occasionally and in small doses.

Generalized forms of fear get well without any trouble; specialized forms in my experience do not, except sometimes spontaneously. In some way perhaps the tissue metabolism is changed by the Franklinization.

Dr. G. BETTON MASSEY—If neurasthenia is caused by fatigue, you would find it in the Adams expressmen, the trunk lifters and carriers. Nerve cells change under the expenditure of energy, but it is a mistake to attribute those changes as an exactly similar condition in neurasthenia. It seems to me that the fatigue neurosis is a relative one.

MELANCHOLIA AND ITS TREATMENT.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY W. S. WATSON, M.D.

RIVERVIEW SANITARIUM, FISHKILL-ON-HUDSON, N. Y.

The symptoms are despondency, sorrow, fear and despair in degree beyond the natural emotions. Anxiety, grief and fear are peculiar to the normal mind and it is only when they exist to such a degree as to be beyond the power of reason and not in harmony with the laws of logic that we may justly style them morbid or call them delusions. Melancholia, as a rule, does not come on abruptly; on the contrary it is a condition of slow growth, with bodily symptoms of so trivial a nature as to scarcely attract attention; notwithstanding, we believe it is more frequently due to physical conditions than otherwise. Melancholia does not necessarily follow neurasthenia. Observation of cases coming under our treatment strongly incline us to the belief that we should look for toxic causes, auto-toxic substances, poisons created within the body, which, step by step, exert a destructive influence over cell formation, while degenerative changes and insanity follow later. We do not pretend that there are no other than physical causes for mental diseases, or that insanity may not be the product of two or more generations or the outgrowth of arrested evolution, powers destroyed or undergoing changes retrograding; we do know that the various mental diseases

imply pathologic implications of the brain; that the brain is touched, in one way or another, and is no more normal in its functions; that its vascular apparatus, its cells, ganglia, meninges or other bearings are involved directly or reflexly. Admitting as we do that the brain is involved in insanity, that it gives expression, we do not concede that the brain is alone or always primarily at fault in mental disturbances, but rather that the mentality of the individual and all the conditions, both physical and psychical, that make up the impressions and expressions are, in fact, the phenomena of insanity.

The nervous symptoms and mental manifestations arising primarily from auto-intoxication due to retained fecal or urinary constituents do not directly produce the nerve reaction: in other words, nerve reaction can not produce infection, except by making infection possible by weakening the defense which a healthy organism naturally offers to the invasion of microbes, or by modifying nutrition so as to develop a medium favorable to low forms of organisms; a weakened or a disturbed nervous system produces defective nutrition, which in turn opens the inroads of infection. Not only are the inroads opened by disturbed nutrition and nerve action, but there also follows an interference in the distribution of the force, which liberates certain substances elaborated by the different organisms by modifying, augmenting or diminishing the normal proportions; hence myxedema is dependent upon perversion of the functions of the thyroids, as will be shown in our enumeration of cases in the course of this paper.

It may be truly said that within the human organism there exists a constant tendency to toxemia from accumulations, and that intoxication can only be avoided by a perfect performance of functional integrity. In melancholia it is the slight exhibitions or manifestations that are of prime importance. The early recognition of the initial symptoms affords an opportunity to ward off an attack that may later lead to insanity. In the melancholic we meet with the self-conscious, or with a lack of buoyancy and self-reliance; morbid fears are more or less marked, so much so as to be justly called delusions, out of which the individual can not be reasoned. Yet there may be no hallucinations whatever. He is aware of his defective judgment and anxious to rid himself of all, yet try as he may, the tendency is to recall, to revert to that which is troubling him whether there be any real foundation or not. There seems to be a lack of power to fix the mind upon anything else; strength of reasoning is gone, a dislike for association with others, a strong aversion to meet those they otherwise know to be their friends is fixed within them; with many there is a periodic aversion to those most dear to them. Instead of the usual marks of affection there are marked explosions of dislike and hatred, jealousy and suspicion. Jealous without the least provocation, jealous of everybody. If it be a married lady, she criticises every move of her husband, suspects every one of her own sex, imagines that all women want her husband, that every little courtesy shown to other women by her husband is meant as a slight to her. Such feelings dominate her entire nature, and her sufferings in consequence are indescribable; jealousy is a marked symptom in the melancholic, and when possible to trace melancholia to its actual source, a very large per cent. originates in domestic unhappiness, disappointed love and incompatibility. In the manage-

ment of such cases much depends upon the environments; separation from all that has surrounded the sufferer during the period of development. Nothing so encourages or feeds the morbid feelings or fires up the outbursts of hatred and dislike as being in the presence of the object of that jealousy, or other unnatural feeling. While it is well and proper to cheer and sustain and soothe our patient by words and acts, it is equally necessary to check and reprove by denying certain indulgences. Separation from relations is oftentimes a cure in itself. The sympathizing acts of relatives tend to increase the morbid imagination already in the mind of the melancholic. We can no better express our reasons for believing it all-important to remove the melancholic from his home than to quote the language of Dr. Pinel. It is, he says, "generally so sweet to an invalid to be in the bosom of his family, there to receive the care and consolation of a tender and compassionate affection, that it is with pain I announce a sad truth, one established by repeated experience; namely, the absolute necessity for confiding the mentally disturbed to the hands of strangers and isolating them from their relatives." It is well to bear in mind that not infrequently family differences and domestic discord are closely connected with the origin of the mental disorder. The successful management of the melancholic not only requires separation from friends and home but the help of those trained to assist—a physician and nurse. To the trained or skilled nurse many of the details of treatment are dependent. A properly selected attendant, one possessing a large amount of patience and endurance, full of humanity, intelligent, zealous in his endeavors to carry out the directions of the physician, is invaluable, and no melancholic case has a reasonable chance of recovery without such constant help and attention as can only be afforded them through proper attendance. Attendants have many privations and discomforts to endure in addition to the responsibility accompanying such a position; and if they be conscientious and diligent, deserve words of commendation and appreciation from those in authority. It is the attendant that hourly hears the complaints, and he needs have a ready answer at all times for the poor melancholic, to offer cheer and to lead the perverted mind into brighter fields. Much, indeed, depends upon the tact of the attendant in imparting hope and in leading the patient to believe his disease is a physical one or dependent upon physical causes. A melancholic patient should never be allowed to understand that his disease is one of the mind. Their greatest fear is that they will become insane. A good attendant will never allow an intimation of mental trouble to be made in the hearing of his patient.

Treatment.—Medicinal therapeutics do not offer anything very satisfactory, although much can and must be done to ameliorate the suffering, imaginary and otherwise. Since constipation is an accompaniment and is either due to natural sluggishness or want of attention, we would commence by giving a brisk calomel purge to unload the accumulations and possible cause of auto-intoxication. Frequently the patient brightens up at once and remains so if the condition of the bowels is watched carefully; but if they are allowed to become inactive there will be almost invariably a relapse. So, in regard to the urinary secretions, careful attention is important. A kidney lesion may and often is an important factor in the accumulation of toxic products. The habit

of defecating at a stated time should be encouraged and required. Antiseptics, as salol, naphthalin, etc., are of value and can be used to some advantage for their local antiseptics on the intestinal tract. Insomnia is a feature of great importance and one controlled with difficulty in many cases. If the true cause of worry can be ascertained and removed an important point is gained; if the circulation is slow and extremities cold, static electricity will do more than all else in procuring sleep, by improving the circulation; if the skin is dry and husky, with coldness of the extremities, Turkish baths with the accompanying rubbing and manipulations are indicated; if such means together with judicious counsel by the physician giving moral support in words do not overcome the sleeplessness then drugs will have to be given. Kola, bromids and chloral are about the safest and best. Codeia we use with considerable success in doses ranging from 0.016 to 0.1 gram, it produces rest and sleep by its inhibitory power over nerve irritability. Hyoscin used hypodermically is of all drugs the one that soothes best and lasts longest. We have never seen an untoward symptom follow its use. It must be remembered that hyoscin is one of our most powerful relaxants, a cerebral sedative and hypnotic; especially indicated in melancholic frenzy and motor excitement.

Systematic exercise, occupying the entire time, is of great importance; giving exercise consistent with the patient's physical condition is very important and tends to divert the mind. Walking, riding, playing games, rowing, chest-weight exercise, dumb bells, etc., are excellent. Thyroid feeding reaches some cases. We have been using thyroid almost since it was first suggested or could be obtained. It has, in our experience, proved curative in one instance, which we shall give. At the present time there are diversified views as to its action. It is our opinion that it will be found of value only in the degenerate conditions and myxedematous cases with possible atrophy of the thyroids. There must, at least, be defective functional activity of the thyroids, since it would seem that they secrete something that acts as an antitoxin and in that way counteracts the tendency to intoxication and consequent mental impairment, or there is in the blood of the mentally disturbed a toxin that the normal thyroid is incapable of antagonizing; hence the necessity for supplying thyroid artificially. It is, we think, pretty conclusive that the thyroids supply to the circulation a substance that is required to maintain its proper composition to sustain brain nutrition, or their secretion prevents auto-intoxication by destroying the poisonous products of metabolism. The results of thyroid treatment at Riverview Sanitarium warrants, we believe, the conclusion that thyroid can not be looked upon as a remedy for mental disease or that it may be generally used in all cases; on the contrary, it is applicable in cretinism and mental degeneracy of insanity. Myxedema is comparatively a new disease, attention having been called to it only about twenty-six years ago, and is primarily a bodily disease. Mental impairment follows after a time. We had great hopes after reading the report of Dr. T. S. Clauston, medical superintendent of the Royal Edinburgh Asylum, in 1892, on the use of thyroid, that a means had been discovered that would reach a large per cent. of insanity cases. Later reports together with our own experience even in mild mental cases, show that our hopes were placed too high. It is,

however, certain that thyroid extract is a therapeutic agent of value in selected cases and that cell changes are affected by it in a remarkable manner; the quickened circulation undoubtedly increases metabolism.

Case 1.—Miss A., age 28 years, admitted March 28, 1896; weight 185 pounds, German descent, American born; showed mental disturbance three years previous but seemed to recover, relapsed May, 1896; when admitted was at times erratic, at others stuporous; slow in decision; strong erotic feelings; myxedematous appearance. Thyroid was given in 0.32 gram doses, t. i. d., for a period of ten days; patient's circulation or pulse rate was increased with complaint of fullness in the head, palpitation, fibrillary twitching of hands, crawling sensations with increased erotic feeling. It was thought best to discontinue the remedy, as there was a general aggravation of the symptoms.

Case 2.—Mrs. R., age 46 years, had been an inmate of an asylum eighteen years previous, during her puerperal state, since which time had remained well. When admitted showed decided nervous symptoms, insomnia, meaningless laughter and extreme restlessness with outbursts of religious excitement. Thyroid was given in 0.32 gram doses the first three days and increased to 0.65 gram, t. i. d., with steady increase of insane symptoms; at the end of third week it was necessary to remove her to an insane asylum.

Case 3.—Miss P., age 33 years; admitted Oct. 12, 1896; had been ill over a year; whole disposition had changed from an active worker and unassuming maiden lady to the belief that she belonged to some man or ought to, showing marked erotism in various ways, whole mind seemed to be upon man, how this or that one could save her, etc. Thyroid was given in increasing doses, beginning with 0.32 gram, t. i. d., believing the extract might be indicated from the degenerate tendency of the mind; after the doses had been increased to 1 gram, t. i. d., the erotism had so increased as to make it necessary to watch the patient every moment, lest she, in her uncontrollable condition, would make a show of herself; every expression and movement as well as words showed intense sexual excitement; the thyroid was discontinued. Hyoscin and codeia was given in moderate doses and in five days the undue sexual feeling was gone. The patient remained under our observation and treatment for a period of three months, when she had recovered to such an extent as to be sent to her friends cured.

Case 4.—Miss A., again on thyroid, Dec. 18, 1896. She is of a neuropathic family, the history is, that an older brother had Basedow's disease at one time in life; at the age of 24 the patient received a shock that seemed to produce a condition of uncertainty and confusion of mind which unfitted her for her work, that of a typewriter and stenographer. For some months she continued to show nervous conditions and mental impairment, at times talked of others having an influence over her and that her thoughts were not her own. She was never truly insane nor so declared, neither was there any necessity for any special restraint; never suicidal or homicidal; sometimes excited, at others depressed, but never to a very unpleasant or unreasonable degree; in such a state she continued for a period of about two years. As time went on she showed signs, in various ways, of increasing erotism, delighting in relating her experience with men and her ideas of man and his relations to women, marriage relations, etc., often expressing the belief that marriage would be a cure for her; physically she presented no marked myxedematous appearance, at least there were no well-defined symptoms of myxedema; there was a strong tendency to increase weight, face was lardaceous and pasty, hands somewhat clubbed and finger struted, skin greasy. Thyroid was given in increasing doses, commencing with 0.32 gram doses, t. i. d.; after the fifth day the doses were 0.65 gram three times a day; at the end of four weeks she was taking 4 grams per day, at which time the improvement was so marked in every respect that she was declared well by one of the leading neurologists of the country: the erotism had all disappeared, she was again the modest girl of former days, improved in every direction; yet we looked upon the case with some degree of suspicion, fearing that by the withdrawal of the drug she might have recurrent symptoms; the state of high tension in the circulation had been kept up for a number of weeks, pulse ranging from 90 to 120 a large part of the time, with but little elevation of temperature or other looked for attendant symptoms while under the thyroid treatment: the urine presented nothing abnormal at any time; some nausea at times and one diarrheal attack during the first six days; under advice it was thought best to gradually withdraw the thyroid and let the circulation come down to its normal rate. The thyroid being reduced to a minimum amount, 0.32 gram per day, close observation was kept over the patient and after

she had been on the minimum amount five days, recurrent symptoms came on; she became disturbed and erratic and a complete relapse followed. After watching the symptoms a few days the thyroid treatment was returned to and given in increasing doses; no apparent change was noticeable until 3 grams per day were given. After the second week the maximum amount of 4 grams daily was given. Decided improvement followed and after being on the full doses one week and a half she showed none of her unnatural symptoms or feelings; in both instances the improvement under the thyroid treatment has been striking and progressive. There can be no doubt as to the cause of the change. We now believe it will be necessary to continue the thyroid treatment for an indefinite time and that her thyroids are defective in supplying a needed element.

While we have not seen such changes as Dr. Clauston of Edinburgh, Dr. C. K. Clark of Kingston, Ont., Dr. Chas. G. Hill of Mt. Hope Retreat, Baltimore, we do believe the thyroid should be tried even though myxedematous appearances are not apparent.

DISCUSSION.

Dr. CANFIELD—My experience with hyoscin in insomnia and melancholia has been very unsatisfactory and I have recently given it a very thorough trial. In one case, the insomnia seemed to vary more than with the dose of trional which I had advised, finding at the beginning that hyoscin was not powerful enough in itself to give any satisfactory sleep. I have found in some other cases that it is more uncertain than almost anything I know of as a hypnotic. Has Dr. Watson found any kind of diet efficient in these cases? I could get no satisfactory results along these lines.

Dr. WATSON—I have not found any line of diet that is worth mentioning as being reliable.

Dr. C. H. HUGHES—When hyoscyamus was first introduced into practice Merck sent me the amorphous hyoscyamus. I tried it to my entire satisfaction. After leaving the asylum I tried it considerably. I recollect a case that began with acute mania, in which the immediate effect was magical, after the ordinary doses of chloral hydrate had failed. I think the result was to prolong that and other cases. I began the use of hyoscyamus about 1872. It seemed not to do the case any good except to produce sleep. In a case of maniacal excitement there is nothing like hyoscyamus. In treating melancholia I always give codeia, in doses adequate to make an impression on the patient and change his psychic feelings; then I withdraw it. It is surprising how small a dose of codeia will suffice in many cases. Less than 0.065 gram is not effective, but 0.13 gram of codeia, combined with aloin given three times or twice a day, after the morning and midday meals, is generally sufficient.

Dr. KINDRED I would favor hyoscin in preference to the other related alkaloid. I have found, as a point of difference in the histologic action of the two, that while hyoscyamus gives a most distinct action as a motor sedative, it does not cause sleep so surely as hyoscin. Hyoscin, in my experience, has acted much more happily than in that of Dr. Canfield. I usually expect to secure from six to eight hours' sleep from a full dose, which I would call $\frac{1}{50}$ grain (0.0015 gram) usually, or, if there be any idiosyncrasy or any danger from giving so much, a dose of $\frac{1}{100}$ grain (0.0007 gram). With regard to diet in melancholia, I would refer to the method employed by Professor Clauston, which he calls over-feeding. It is only a system of filling the economy with albuminous material. He uses pure milk and egg, sometimes combined with vegetable food in the form of liquid extract. He gives from a pint to a quart of this albuminous mixture, every three or four hours. That, I believe, has the advantage which he claims of building up the nutrition as rapidly as possible, as is necessary in melancholia, which is the result of mal-nutrition. But it has the further advantage of leaving as little residuum and debris in the intestinal canal as possible. Since, as Dr. Watson claims, this condition may even result from auto-intoxication, that is an important point in treating melancholia.

In reply to a query Dr. Hughes stated that he did not use hyoscin to the exclusion of chloral hydrate or some form of bromid, preferably bromid of sodium. He would not rely on hyoscin except as a pure hypnotic to coerce sleep in cases in which the necessity for bringing about sleep immediately is imperative. He did not use hyoscyamus at all.

Dr. WATSON In regard to the use of bromid of sodium in such doses as 4 grams or more, I very frequently find that my patient seems to be more depressed afterward, while the less frequent doses of hyoscin seem to have a less disastrous effect. Bromid in combination with strong bitter tonics may sometimes be safely used.

RUMINATION IN MAN.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June, 1-4, 1897.

BY WHARTON SINKLER, M.D.

PHILADELPHIA, PA.

Merycism, or rumination in man, although described by ancient medical writers, has attracted but little attention until within the past few years. Hammond, who reported a case in 1894, said that only about fifty cases had been recorded up to that time. Since then, however, a number of additional cases have been recorded, both in this country and abroad. I have however been able to find only thirteen reported in America, but in Europe a great number of cases have been added to the literature in recent years. The American cases are:

Hubbard: *Medical Record*, 1886, p. 122, one case.

Max Einhorn: *Medical Record*, 1890, p. 38, two cases.

Charles Shattinger: *Medical Fortnightly*, 1892, p. 163, one case.

W. A. Hammond: *Proceedings of American Neurological Association*, 1894, one case.

D. W. Graham: *Chicago Medical Examiner*, 1894, Vol. xv, p. 118, one case.

Edward Runge: *St. Louis Med. Review*, 1894, p. 121, one case.

Edward Runge: *Boston Med. and Surg. Journal*, 1895, Vol. cxxxii, p. 575, three cases.

Albert Abrahams: *Medical News*, 1895, p. 405, one case.

David Riesman: *Journ. of Nervous and Mental Diseases*, 1895, two cases.

It is probable that a great number of mericoles exist whose cases have not been reported, being regarded by their physicians as cases of ordinary indigestion with vomiting. It is also likely that many persons who have the habit of regurgitation of their food are withheld from saying anything about it, either because they do not think it worth while to consult a physician, or because they are ashamed to speak of it. Brown-Séquard and Blanchard were mericoles, and the latter has written a treatise on rumination.

The disorder was described very fully by the great Italian anatomist, Fabricius ab Aquapendente, in 1687. He seems, however, to have been somewhat tainted with superstition in regard to the subject, for he describes two cases of merycismus, one of which was a nobleman alleged to have two horns on his forehead, and the other was a monk whose father had a little horn on the forehead (Lemoine and Linossier, *Rev. de Méd.*, 1894, p. 177). Pipelet wrote the first really scientific paper on the subject, in 1786.

Rumination or merycism must not be regarded as the simple regurgitation or vomiting of food. It is a return of the food shortly after it has been swallowed, unattended by nausea, retching or disgust. In many cases only the portions of food which need remastication are returned. The regurgitated food is either rejected from the mouth, or it is remasticated and again swallowed. The act of rumination in man is analogous to the process of rumination or chewing the cud in certain of the lower animals. This act in the herbivorous animal is probably the result of evolution. Blanchard (on rumination, "Handbook of the Medical Sciences," Vol. viii) says that "the habit of rumination was acquired by certain animals at the time that the carnivora first appeared upon the earth. Fearful of attack, the ruminants grazed rapidly, ready for flight at the first intimation of danger; then, having reached a place of safety, their food was regurgitated and masticated thoroughly." "A similar condition"

he asserts, "is obtaining in man in this age of hurry, and unless we learn to be more deliberate in our eating, and masticate our food in the first instance more carefully, the interests of digestion will compel the regurgitation and re-chewing of the food which has been so imperfectly prepared for the action upon it of the gastric and intestinal secretions, and in time this process, which is now exceptional in man, will become habitual." This, we hope, is a fanciful idea on the part of the writer. Man will first have to acquire a digestive organ similar to that of the ruminants before he can begin the same process of digestion as they have. In the young of the ruminants, the stomach is a simple organ consisting entirely of the abomasum or rennet. As the animal grows older and begins to eat grass, the stomach becomes divided into other compartments, and in adult life the stomach is a large and complicated organ, consisting of four distinct compartments—the rumen or paunch, the reticulum or honey-comb bag, the psalter and the abomasum or rennet. The food, after its first imperfect mastication, passes into the first and second stomachs. After a short time, dependent upon circumstances, the food is regurgitated into the mouth where it is remasticated and then swallowed in a state of fine subdivision which permits it to pass through the narrow aperture between the reticulum and the psalter. Then the food passes into the abomasum or true stomach, and is there subjected to the action of the digestive juices. In the act of regurgitation two factors are present, one the lessening of the intra-thoracic pressure, and the other the aspiration of the gastric contents. The stomach itself is probably a passive agent in the act of regurgitation, as it is in the act of vomiting. There is, however, an anti-peristaltic movement in the esophagus as soon as the bolus enters this canal.

Rumination is a reflex act and is controlled by a center in the medulla oblongata. The nerves concerned are the pneumogastric, the phrenic, and the motor nerves of the abdomen, stomach and the esophagus. The process of rumination in man has been carefully studied by several writers, and is regarded by all as being practically identical in its mechanism with that of the herbivora; "the factor of paramount importance being the closure of the glottis and the descent of the diaphragm, but while the mode of its production has been quite fully elucidated, we are still ignorant of its ultimate cause."¹

No constant anatomic lesions have been noted. The lower end of the esophagus has been found dilated in one or two cases, but this has not always been observed and, on the other hand, a dilatation of the cardiac end of the esophagus has been found in cases that did not present rumination.

The causes of rumination have been variously assigned by different writers, but the majority of observers agree that in nearly all cases of merycism there is a neurotic diathesis, and that neurasthenia plays a large part in the production of the affection. Lemoin and Linossier (op. cit.), who have collected a number of cases, believe that the majority of mericoles are neurasthenic. These authors explain the process as a means of correcting acidity, the salivary juices diminishing it in each act of reswallowing. Singer ("xxx," *Deutsches Archiv für Klin. Med.*, 1893, No. 1, p. 503), in an elaborate article on the subject of rumination, gives the following conclusions: "1, rumination and regurgitation ought to be identical

with each other; 2, rumination is the expression of a nervous constitution; 3, the next reason for the condition is the relative insufficiency of the cardia; 4, the mechanism consists of an aspiration of the stomach contents into the relaxed cardia by reason of the ramification of the air in the thorax, occasioned by a simultaneous expiratory act of the closure of the glottis; 5, the regurgitation of the food can be prevented by expiratory acts; 6, the *antrum cardiacum* corresponds to a widening of the esophagus, demonstrable in life; it occurs from stretching, by swallowing large pieces of food; 7, rumination is to be differentiated physiologically and clinically from vomiting; the only form that it can be allied to is nervous vomiting; 8, the relation of the function of the stomach is constant, and has the complex symptom of rumination in all the significance of an accidental occurrence; 9, regurgitation in diverticular formation and in dilatation of the esophagus is different from rumination in the predominance of difficulty in swallowing; 10, hasty eating and much fluid drink must be avoided; medication should be directed to tone up the cardia."

My own experience, and that of the writers above quoted, lead me to believe that in the great majority of cases rumination is dependent on a condition of either neurasthenia or hysteria and that it rarely occurs in healthy persons, although this may be the case. Heredity undoubtedly plays a part in the causation of the disease and this may be indirectly through a neurotic diathesis, or the disease may be directly transmitted as in the case recorded by Runge, (*Boston Med. and Surg. Jour.*, 1895, p. 515). In this instance a father, son and son's son were all mericoles. In a case reported by Lemoin and Linossier the patient had a brother who had the habit of merycism. Two varieties of rumination are observed; one which depends upon a previous condition of gastric indigestion and the other which is simply a habit or it may be the expression of a neurasthenic condition. In other words, there is a digestive and a neuropathic merycism. In most mericoles the process is perfectly natural and if this is interfered with they suffer some discomfort or some stomach disarrangement occurs. A German physician, Nacke (quoted by Riesmann), who is a sufferer from this affection and who has studied his own case carefully, is convinced of its relation to neurasthenia, for he found that whenever the nervous system was most unstable the rumination was most energetic. Singer (op. cit.) says, that the act of rumination is prevented by sexual excitement. Runge (*St. Louis Medical Review*, Aug, 18, 1894) has reported an interesting case of rumination and has advanced a very ingenious theory as to atavism as a cause of merycism. The arguments which he advances are the development of the stomach by the laws of natural selection by which the conditions of the animal are adapted to the environments. We can scarcely accept this theory, as the connection between man and the ruminant with his four stomachs is too remote. The manner of eating and the character of the food eaten has, no doubt, much to do with the production of rumination in persons predisposed to nervous disorders. Hasty eating and imperfect chewing and drinking much liquid with meals is a frequent cause. Rumination may be the result of imitation, as seen in the case of two children reported by Koerner (*Deutsches Archiv für Klin. Med.*, Bd. xxxii, p. 554). Their governess was in the habit of regurgitating her food and the chil-

¹ Riesman: *Journal of Nervous and Mental Disease*, June, 1895.

dren copied the practice; they were cured when the governess was sent away.

The symptoms of rumination are very constant. As a rule, at a period varying from a half hour to an hour after a meal, the patient begins to have a return of the food into the mouth. This occurs without any discomfort or nausea and generally without gas. The patient is usually unaware that regurgitation is about to take place. The food tastes pleasant and the patient usually swallows it again immediately, or if there be any large particles of food which have been imperfectly masticated, rechews and swallows them. Most patients declare that the different articles of food can be tasted and discriminated from each other. A patient, whose case is related by Riesman, said that when he drank beer it was returned and tasted more pleasantly than it did at first. Other writers have found that mericoles assert that the food tastes pleasant when regurgitated. The period of rumination lasts from a half hour to two hours and then ceases. At times a condition of hyperacidity of the gastric contents is found, but a large number of examinations made by different writers show that there is no constancy in regard to this condition. In dyspeptic rumination the food which is rejected may have a sour and disagreeable taste.

The following cases of rumination have come under my own observation:

Case 1.—Robert G., aged 20 years, waiter, referred by Dr. Thomas C. Potter. The family history of the patient was practically negative with the exception of neurasthenia in a sister. There is no knowledge of nervous disease or of the disease from which the patient suffers. In his childhood he had measles, urticaria and subject to rheumatism. Syphilis is denied and he says that his habits are good regarding alcohol and tobacco. He applied at the Orthopedic Hospital and Infirmary for Nervous Diseases, September, 1896, for the relief of nervousness, insomnia, general trembling and indigestion. The extreme nervousness was of recent date, but the indigestion was of ten years duration. It was found upon inquiry that since the age of 10 years he had been in the habit of regurgitating his food soon after it had been taken. The regurgitation began at various periods after eating; often immediately after a meal and never later than a half hour after. The act occurred irregularly at first, but soon became a constant occurrence. The intervals have varied, and lasted from three to nine hours after eating, though usually the period was from two to three hours. The food is agreeable in taste at first, but toward the latter part of the period of regurgitation becomes disagreeable and the patient has some discomfort of digestion. The amount regurgitated usually fills the mouth. While in a recumbent position there is usually some abatement in the symptoms, but it is never entirely prevented. It never occurs during sleep, but may continue for a half hour after he has gone to bed. If he makes an effort to restrain the act there is pain in the epigastrium. The food often fills the mouth before he is aware of regurgitation, but there are times in which it may be felt rising from the stomach through the esophagus. If rejected from the mouth the food is found to be in a mushy or semiliquid state and if allowed to settle forms two layers; a liquid layer below and a white curdy layer above. Milk is returned curdled but not sour. He asserts that he has always been discreet in his diet, chewing his food thoroughly before and since the onset of the disorder, and he can give no explanation as to its development. An examination of the patient shows a generally neurasthenic state. He has the usual subjective sensations of the condition, such as a sense of bulging of the temples, pressure and pain at the nape of the neck and heaviness about the eyes. He is very nervous and exhibits a general tremor when excited. Knee jerks are active but not spastic and there is pseudo clonus of the left ankle. Pupils are normal; there is no motor paralysis or sensory change. The heart and lungs are normal: the appetite is poor; the bowels constipated and the tongue is coated. An examination of the epigastric and hypochondriac regions disclosed no abnormality in the area of stomach tympany.

Case 2.—Harry B., aged 39 years, works in a butcher shop, married. Applied for treatment Nov. 12, 1894. Has had good

health until somewhat more than a year ago, when he began to suffer from severe frontal and temporal headaches. These headaches answered the description of migraine and occurred after excessive use of the eyes or exposure to unusual excitement. His family history is negative as is also the personal history previous to the present trouble. He has been temperate in his habits and has had no serious illness. For a year he has had regurgitation of food, especially after taking any indigestible substances. The food is returned almost immediately after eating and is not disagreeable to the taste. It is usually swallowed without being rechewed. The patient has more or less indigestion and a sense of epigastric discomfort after eating. The condition on examination is as follows: General nutrition fair; tongue coated, flabby, glossy, and is tremulous on protrusion. The patient is in a general neurasthenic condition. He complains of fullness in the head; has a poor memory and the eyelids are tremulous. The attacks of headache occur about once a week. The eyes were found to be astigmatic. The reflexes were normal and the urine showed no sign of kidney disease. The act of regurgitation occurs now after almost every meal. The patient was treated with cannabis indica and regimen directed to the relief of his neurasthenic condition. The regurgitation was entirely relieved and had not reappeared when the patient was last seen after an interval of about six months.

The two following cases are not instances of typical rumination because the food is not reswallowed after regurgitation from the stomach, but the process is allied to that of merycism.

Case 3.—Mary W., aged 5 years, was brought to the Orthopedic Hospital and Infirmary for Nervous Diseases March 18, 1895, with the statement that she had vomited every meal immediately after eating. The food was returned within about ten minutes after its ingestion; there was never any nausea and the food was but little changed in appearance; it was never remasticated nor reswallowed. There was nothing of note in the family history except that a maternal cousin was an epileptic. The patient was born at term without complications; speech was developed normally; she walked early and the teeth were cut in good time. Except an attack of measles and whooping cough at about 4 years of age, the patient has had no ill health. The patient's condition was as follows: Her general nutrition was fairly good; face flushed; appetite good; slept well; no headache; knee jerks were normal; heart and lungs normal; patient's mental state was slightly below par.

Case 4.—Miss G., aged 30 years, has for years been exceedingly neurotic and hysteric. Her mother is nervous and at least one of her sisters is of a highly nervous temperament. For years she has been eccentric in her eating and has refused to take food, except in the smallest amounts, for periods of several months, so that she has at times become emaciated to the last degree. She has been in the habit of taking champagne, to the amount of about a pint a day, for the past two or three years and for several months has taken chloral to induce sleep. She is irritable and exceedingly perverse. She has been in the habit for some years of regurgitating her food immediately after it is eaten. The food is brought up in large quantities, more by an act of vomiting than true regurgitation, but the act is performed without nausea or effort. The food is not disagreeable in taste or odor. There are intervals when the patient retains her food, but it depends rather more upon inclination than otherwise.

Prognosis.—The prospect of recovery in rumination is not good and this would naturally be inferred from the nature of the affection. Many cases improve to a great extent under appropriate treatment and often with no treatment there are intermissions of one to three years, but sooner or later there is a return of the habit. In many cases patients voluntarily return to the practice of rumination, either because they like to retaste the food or the regurgitation of the food relieves some gastric distress.

Treatment.—This consists mainly in attention to the general health of the patient. There is generally a neurasthenic condition and this should be relieved if possible by an appropriate line of management. In many cases the habit of rumination will be arrested as long as the patient's general health is up to standard and there is a return of the trouble as soon as

there is any failure in the general health or recurrence of the neurasthenia.

In one of the cases which I have reported, the rumination ceased when the patient's general health had improved and did not return as long as he was under observation, although the attacks of migraine, for which he had originally come for treatment, persisted. There are practically no therapeutic measures of use in these cases, with the exception possibly of nerve sedatives and tonics. If there is gastric indigestion this must be corrected. Lavage is an important procedure in the management of cases of rumination dependent upon indigestion. The diet should be carefully regulated, and what is of great importance, the amount of liquid taken with a meal should be reduced to a minimum. Thorough and complete mastication of the food is also an essential matter in this disease. The patient should be trained to control the inclination to regurgitation of the food. Hypnotic suggestion will probably prove useful in the management of such cases, although I have seen no record of any treatment by this measure. Hammond stated that the patient whose case he reported before the American Neurological Association was mentally defective, and with a view of relieving the psychical condition he trephined the skull, first in one parietal region and then in the other. The mercism ceased after the first operation and had not returned at the time that the case was reported. In this instance, no doubt, the checking of rumination was due to suggestion.

DISCUSSION.

Dr. JAMES HENDRIE LLOYD—This would seem to be a neurotic state allied to the condition of hysteric vomiting. I do not think in hysteric vomiting it is common to have true rumination, and there is constant attempt at retching—probably more a condition of esophagismus, a tendency to regurgitate through the esophagus. In an idiotic child that came under my observation there was regurgitation from the mouth, the food being disgorged, reintroduced into the mouth and eaten over again. The procedure resorted to in the case reported by Dr. Hammond seems hardly worthy of being followed. The treatment is by suggestion, and we can get ideas into people's skulls without making holes to put them in!

Dr. CHARLES H. HUGHES—I think the better treatment is by digestion rather than suggestion. I have been accustomed to associate the majority of these cases with conditions of dyspepsia in persons of neuropathic diathesis. I have seen these cases in neurasthenia. When I first read Trousseau on "Apepsia Nervosa," and subsequently gained a great deal of experience with nervous dyspeptics, I found that there were many of these conditions in which regurgitation took place and in some instances the food was rechewed.

Dr. SINKLER—I think the point is that rumination is not a condition of indigestion; the food when returned is sweet and pleasant. As soon as it becomes fit for intestinal absorption it passes out of the stomach and ceases to be returned to the mouth. Dr. Lloyd's remarks remind me that several cases of rumination have been reported in idiots. There is one suggestion that can be made in regard to this habit, that it is a form of digestive perversion like sexual perversion. I think a lack of thorough mastication is probably one of the primary causes.

dren, three of whom are living and in good health. She was always of a nervous, somewhat irritable, temperament, but mentally bright and clever, with linguistic and other accomplishments. After the birth of her first child she had an attack of mania; when about 23 years of age she had an attack of chorea which lasted several weeks. At 35 years of age, apparently as the result of unusual worry owing to sickness, she became more irritable and her temper was afterward capricious. For about ten years previous to her death she was subject to spells of excitement which almost amounted to transient derangement, but she had no tangible delusions, although she had a tendency to persecutory ideas, frequently believing without cause that she was abused and ill-treated by others. During the same period she began to show a decided amnesia for names, this gradually but surely increasing, so that for several years before her death it was almost impossible for her to recall the names of acquaintances, and occasionally of objects with which she was familiar. She had, however, no motor aphasia and could converse and write well, having an unusual facility for letter writing until within three years of her death.

FIG. 1.—Long pyramidal cells, showing moniliform swellings of basilar and apical dendrites. Region of second frontal convolution.

Up to this time she had been less vigorous, but always attended to her business affairs, kept house and performed what other duties she had to do. During this third year previous to death she became so unreasonable that it was impossible to live peaceably with her, she having at times outbursts of uncontrollable passion. General failure of memory was first noticed about two years before death, during which time she became half bedridden.

In January, 1895, she had what appeared to be an attack of grippe; there was rise of temperature and she complained of intense pain in the right side of the head, also of pain in the back, extending down the legs in the course of the sciatic nerve. This attack lasted about a week and she apparently regained her usual health. In March of the same year she had a second attack, which was also accompanied by intense backache and pain in the head, the latter pain being persistent and always referred to the right parietal region. The patient did not improve as she

A CLINICAL AND PATHOLOGIC REPORT OF A CASE OF PROGRESSIVE DEMENTIA.¹

Presented in the Section on Neurology and Medical Jurisprudence, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, June 1-4, 1897.

BY CHARLES K. MILLS, M.D., AND
MARY A. SCHIVELY, M.D.

PHILADELPHIA, PA.

The case under consideration presents the following history:

Patient aged 64 years; married; has had five chil-

¹ An abstract of a portion of this paper, with other illustrations, has been published as a "Preliminary Report," in the Proceedings of the American Medico-Psychological Association for 1897.

had done after the previous attack, except that the lumbar pain diminished. There was marked insomnia.

After two or three weeks she began to have marked delusions, which related to her surroundings and also to her children. She believed that she had been taken away from home and was living in a strange house. She spoke of having visits from her father and mother, both of whom had been dead for many years. Sleep was only obtained by the use of hypnotics.

In April, 1895, a consultation was held by Drs. Sinkler and Mills. At this time the patient had marked delusions, talked volubly and at random; was unable to walk without assistance and if she attempted to do so staggered, always pitching to one side.

During the last eighteen months of her life she was confined to bed continuously. Her chief symptoms during this time were vertiginous attacks; difficulty in orientating; marked amnesia, not only for names but for recent events. She gradually became feebler mentally and a few months before her death was in a state of decided dementia, with occasional periods of excitement. Her attempts at conversation were childish and incoherent; she had numerous unsystematized delusions; she failed to recognize her children and attendants and lost memory of everything.

FIG. 2.—Long pyramidal cell from the second frontal convolution, showing roughening and swelling of the apical dendrite; deformity and loss of basilar dendrites; absence of gemmulae.

An ophthalmoscopic examination made in April, 1895, and again in the early part of 1896, revealed no change in the fundus. One pupil was dilated. There were no bed sores, and no paralysis at any time.

November 5, 1896, she became suddenly comatose and died the next day. The case was one in which the entire fabric of the mind seemed gradually to break up, and step by step with failure of physical powers mental failure progressed.

The postmortem examination made by Drs. Burr and Kelly, November 7, revealed the following pathologic conditions: The dura was somewhat thickened; the pia-arachnoid opaque. The internal carotid, posterior communicans and basilar arteries were atheromatous; the left anterior communicans showed aneurysmal dilatation. Miliary aneurysms of the pial

vessels were present on the ventral surface of the pons. Portions from six regions of the cortex were hardened in alcohol, the remainder of the brain was placed in Müller's fluid.

FIG. 3.—Purkinje cells of cerebellum, showing atrophy of the dendrites; stumpy branches in place of feathery dendrites.

FIG. 4.—Protoplasmic glia cells from middle occipital region; some presenting a botryoidal appearance, others showing stages of disintegration.

The methods employed in the microscopic examination of the brain were the following: The silver phospho-molybdate method of Berkley; Nissl's methylene blue; thionin according to Lenhossek; Weigert Pal; eosin and hematoxylin; also hematoxylin, picric acid and fuchsin. (Van Gieson.)

Microscopic examination reveals the following pathologic conditions:

The neuron shows internal changes which consist in deeper staining of the cell body; the chromophilic particles are irregularly arranged; absent from some areas and aggregated in others, giving the protoplasm a vacuolated appearance. In most cases the chromophilic particles are arranged as a layer of fine dust around the nucleus, next there is a surrounding clear space and beyond this a layer, either continuous or interrupted, of chromophilic particles along the cell wall. The chromophilic particles of the cell processes are either wanting or sparsely scattered throughout. The nucleus is regular in contour; the larger chromophilic particles are absent, while the finer dust-like particles and normally clear karyoplasm stain irregularly. The nucleolus is somewhat increased in size and shows a markedly increased receptivity to stain.

External changes in the neuron are shown in roughening deformity and in some cases excavation of the cell-corpus. The basilar dendrites show moniliform swellings along their course, or are shortened, with

are areas of atheromatous degeneration. The elastic lamina is intact. Both vessels contain thrombi.

The left posterior communicans is twice the diameter of the right. In both, the intima, media and adventitia are equally thickened, and thrombi are present.

FIG. 5.—Section in region of second temporal convolution, showing thickening of the pia-arachnoid, stasis and over-distension of cortical vessels.

clubbed extremities, or some of the dendrites are absent. The apical dendrite is roughened and irregular in contour. The fine collaterals and terminals are wrinkled and irregular in contour. Gemmule are absent in the regions of moniliform swellings of the dendrites and at other points. The long pyramidal cells seem to be most affected, although similar changes do occur in the fusiform and polymorphic cells they are not so marked. These changes of the neuron are not limited to any special region of the cortex. The Purkinje cells of the cerebellum show thickened stems with short stumpy branches in place of the feathery dendrites of the normal cell.

The basilar and internal carotid arteries show an increase in the number of endothelial cells and a growth of new connective tissue derived from the endothelium. This growth consists of branching cells, proliferated nuclei and basement substance, the latter being very dense. Scattered through this new growth

FIG. 6.—Section of the right optic nerve, showing similar changes to those found in the cortical vessels.

FIG. 7.—Section of optic chiasm; similar vascular changes.

The anterior communicans exhibits aneurysmal dilation; the endothelium is absent; there is proliferation of adventitial elements with increase in basement substance, the latter being so marked as to give the whole vessel wall a hyaline appearance. There are areas of atheromatous degeneration in this increased basement substance; the elastic lamina is absent. The vessel wall opposite to this thickened area shows

absence of the media and thinning of the adventitia. The vessel contains recent and partially organized thrombi.

The pia is increased in thickness shows nuclear proliferation and evidences of extravasated blood in the form of groups of corpuscles and hematoidin crystals. The pial vessels show thickening of their walls and stasis; they are markedly tortuous and present aneurysmal dilatations in their course. Miliary aneurysms found on the ventral surface of the pons have the appearance of grape-like clusters. On section the walls of these vessels show nuclear proliferation of the protoplasmic cells of the adventitia, also extravasation of blood corpuscles and pigment into the spaces between individual vessels. Stasis and over-distension is marked.

The cortical vessels of all sizes are over-distended with blood corpuscles; they are exceedingly irregular and tortuous in their course (many being twisted several times upon themselves); they appear much more numerous than normal. The perivascular lymph-

FIG. 8.—Transverse section of vessels of anterior perforated space, showing stasis, thickening of their walls and distension of the perivascular lymphatic space.

phatics are distended, showing wide spaces between the vessel sheath and the brain substance. The pericellular lymph spaces are also enlarged.

The protoplasmic glia cells present a series of transitional changes; their fine mossy granulation appearance is lost; the pseudopodia show varicose swellings in their course, thus far they retain their vascular attachment. Many cells show an irregular botryoidal appearance and loss of vascular attachment. Finally, evidences of disintegration of cells is to be observed. Deiter's cells are numerous both in cerebrum and cerebellum.

Areas of softening occur in right ascending parietal region, they consist of a reticulated stroma surrounding a central cavity which contains portions of blood vessels; groups of blood corpuscles, hematoidin crystals and fragments of nerve and neuroglia tissue. Areas of coagulation necrosis are present in the left ascending parietal region.

Medullated fibers show different stages of myelin

degeneration; these appearances are demonstrable in the ascending parietal region, the optic chiasm and in irregularly scattered areas of the pons and medulla.

The pathologic conditions occurring in this case of progressive dementia may be summarized as follows: 1, internal and external changes of the neuron; 2, changes involving the cortical and pial vessels, also the vessels of the base of the brain; 3, changes in the protoplasmic glia cells; 4, multiple areas of softening in the ascending parietal region; 5, myelin degeneration.

FIG. 9.—Section of cerebellum, showing over-distension and multiplication of vessels.

FIG. 10.—Tortuous vessels from the ascending parietal region.

The above described changes in the neuron correspond to those found by Berkley in experimentation upon alcohol poisoning, and in examination of cases of alcoholic dementia. They also correspond to the changes described by Andriezen as occurring in alcoholic dementia and other insanities. A survey of the views of these authors upon the pathology of insanity is therefore in order.

Berkley considers that conduction of the nerve stimuli to the cell corpus takes place principally through the medium of the gemmula, and that these are the

first division of the neuron to atrophy. If the gemulæ lose their vitality or become diseased conduction of impulses is impossible. Inco-ordination of thought and motion would then result from loss of direction as well as from want of originative impulses. Permanent dementia would be the result of the degenerative process involving a large number of cortical neurons.

FIG. 11.—Section of atheromatous portion of the basilar artery.

FIG. 12.—Miliary aneurysms, pial vessels ventral surface of the pons.

According to Andriezen the series of early changes in dementia illustrated by insomnia, amnesia, incapacity for attention and mental exertion and fatigue can be explained pathologically by progressive nutritive and dynamic changes. The nerve cell of the dement is stimulated beyond its average limits and at a greater pace than it would be in health. As he describes it, "The result is quickness, rapidity and over-

flow of ideas followed by fatigue and drowsiness, and this in turn by a sub-conscious condition in which there is a continuous and distressing whirl of nerve currents through the brain." The repetition of such attacks causes permanent damage to the nerve cell. Delusions of suspicion and maniacal outbursts are explained by him as the result of destruction of the neuro-protoplasmic plexus of the molecular and ambiguous layers.

DISCUSSION.

Dr. CHARLES K. MILLS—The lady was a patient in private

practice. There was no possibility of either alcoholism, syphilis, or any of the common exciting or predisposing causes of insanity of this kind being present, so it furnishes us with a non specific and non-alcoholic case. This case is interesting in connection with the entire question of neurasthenia, and also in relation to the pathology of melancholia and non-specific dementia. The paper bears out the views advanced by Dr. Dercum, which we endeavored to place upon a firm basis of the pathology of neurasthenia, and bears out the views as perhaps best elaborated in the remarkable series of papers which were eventually put into a monograph by Dr. Cowles of Boston, on "Neurasthenia and the Development of Insanity." Doubtless this patient had some inherent tendency to mental disorder, but that does not alter the question as to the bearing of these investigations upon the pathology of the subject.

Dr. F. X. DERCUM—My own conception of the pathology of insanity, presented some years ago, is about as follows: It embraced the changes more especially in the neurons, but especially did I lay stress on the possible toxic causes of insanity. There are a great many facts to prove that we have toxins circulating in the blood; certainly the toxicity of the urine is very pronounced in some forms of insanity, while it is diminished in others. It is diminished, for instance, in melancholia, while the toxicity of the blood is increased in mania.

It seems that these changes in the nerves and blood vessels are only referable to some irritant, something that necroses the collaterals, the dendrites, and that destroys the chemic constitution of the protoplasm in the nerve cell.

Here we have changes taking place in a non-specific and non-alcoholic case, and yet, to my mind, there must have been some substance in the blood which acted in this destructive manner upon these delicate structures in the brain and in the nerve centers. When we have a case that appears to be auto-toxic the general autopsy is of the utmost importance. In this case the most elaborate studies would have been repaid, including the study of the viscera as a whole, and of the bone marrow. Even studies of the blood in the dead subject might have been repaid. We see here terminal changes, resulting changes; the primary cause is still to be sought after. In the various laboratories of the State hospitals for the insane a large amount of work should be done, not only upon the dead brain, but upon the living individuals, and it should be largely experimental in character. We are still far behind in our knowledge of the chemistry of the urine, and we have to adopt coarse physiologic methods to determine the presence of toxic bodies there. Especially should there be experiments as to the changes which arise in the nerve cells of guinea pigs to see whether they are similar to the changes which occur in the human. In the same way we ought to experiment with the serum of the blood of the insane.

ALCOHOL AS A CAUSATIVE FACTOR IN DISEASES OF THE CENTRAL NERVOUS SYSTEM.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY T. D. CROTHERS, M.D.

SUPERINTENDENT OF WALNUT LODGE HOSPITAL,
HARTFORD, CONN.

Next to syphilis, alcohol is the most frequent cause of diseases of the brain. In many instances it is more virulent, rapid and pronounced in its effects and is now fully recognized as a poison of the narcotic class.

Its general action on the system is seen in irritation, deranged functional activities, diminished force and narcosis. Some instances show marked narcosis from the beginning. The first effect of alcohol is to produce functional disturbance, and such poisons are called narcotic and neurotic, because their most conspicuous action is on the nervous system. Apparently this effect is transient, and the injury is supposed to be indicated by the repetition of the functional disturbances. A fatal dose acts like other tissue poisons, producing narcosis and necrosis. Alcohol while being carried to all parts of the body acts, like other poisons, on those parts which it reaches with the least amount of dilution, particularly the stomach and liver. Unlike

other poisons, it seems to have a special affinity for the brain and nervous system. The vascular disturbance and consequent nutritional derangement are most prominent. The effects of alcohol in what are called chronic states, may vary widely in persons who are termed steady drinkers, and others who are not supposed to be injured by alcohol, up to those who are notoriously degenerated from its use, may be grouped as follows:

1. General temporary exaltation of the brain and emotional activities, followed by depression and feebleness, loss of memory and change of character and conduct.
2. General diminished power of attention and volition, particularly in the sensorial and kinesthetic centers and their connections.
3. Diminished energy and adaptability of conduct to the conditions of life.
4. Diminished muscular power and demand for help or stimuli to do the ordinary work of the system.
5. From the first a marked blunting and deepening obscurity of the moral and ethical sense.
6. Insomnia, diminished power of sleep and recuperation, with a nutritive break down of the stomach and brain.
7. The relations of the *ego* to the external world become disturbed followed by melancholy, suspicion, delusions, hallucinations and changed emotional states all merging into various chronic insanities.

These groups of symptoms are seen in all cases, not in a continuous order, but varying widely. Sometimes one is much more prominent than the other, but in all cases the psychical disturbances are present. The diminished sensory functions and the lowering and obscuring of the higher ethical sense of duty and the relation to the surroundings indicate a profound nutritive and dynamic failure of the nerve elements of the brain. While these are the well-marked symptoms of all cases who use alcohol excessively they are by no means absent in those who are supposed to use it in moderation. There are no dividing lines on one side of which the poisonous action of alcohol can be seen, while on the other it is absent. The fact is that alcohol, like other poisons, varies in its effects on different persons, producing in certain organs more prominent effects than in others; in certain cases concealed for a long time, then bursting out, revealing a degree of degeneration unsuspected; concentrating on the liver, stomach, kidneys or heart, or suddenly developing into serious lesions of the higher brain centers.

To understand more clearly the influence of alcohol in the causation of disease of the central nervous system, a study of some central facts of the dynamics of brain energy and force will be useful. All nerve force and brain activity is physical energy in motion. This energy is gathered and released and is technically only a variety of motion the same as is electricity. It is transmitted motion, but not electricity, although the latter is transmitted in the same way. It comes from nutrition, from chemic and molecular changes and is stored up and released by certain activities. It may be quickened, retarded, changed, increased or withdrawn.

It is the transmission of this energy along the nerve tracts to all parts of the body that constitutes life, and with all its attractions and repulsions and the continual readjustments of the delicate equilibrium necessary to sustain the work of life this is carried on with exact and absolute precision. Nothing in the

range of human knowledge can compare with the perfection and minuteness of these dynamic processes going on in the neurons and protoplasm of the brain. The force displayed in muscular activity, the contraction and expansion of the molecules as energy is liberated and transmitted along the fibers, well illustrates the marvelous mechanism of the brain.

This energy can be changed by foods, by drugs, by environments, all of these being new sources of energy, which may add to or pervert and exhaust the present sources, or more commonly may change the direction and power of this energy or depress it below normal levels. This is clear from a change of function and normal activity of the body. What we call disease is a change of the chemic conditions of the body and consequent alterations of nerve force and energy.

This is noted first in deranged functions and disturbed energies, which seem to act out of harmony with the surroundings. Functional disturbance may reach a point where it becomes convulsive and displays a flow of energy along new paths of discharge. What is called nerve-storms is the unrestrained convulsive concentration of nerve force and the repetition of this, in epilepsy, is disease. Drugs which change this release of energy may be dangerous, in not only destroying the equilibrium of forces, but the power of adding new energies and increasing or diminishing the direction and rapidity of the energy. This gives some conception of the mechanism of what is called inhibition and resistance. In early life the energies of the body may be easily augmented and perverted. The functional changes may register these states. In later life defective nutrition and chemic changes break up the normal flow of energy. This breaking up of nerve energy and irregularity of the movement of nerve force is most strikingly seen in epilepsy and convulsive irregular discharges of nerve and muscular power. This energy is renewed during a period of building up; then it is released in a convulsive discharge of force. These are some of the facts which bring us to a point of view where the action of alcohol can be seen more clearly. The fact that alcohol, even in small doses, produces functional disturbances in the brain and nervous system is very significant of derangement of nerve energy and motion.

Another fact admitted beyond all controversy is that alcohol has a special affinity and positive action over the brain and nervous system. Its effects are seen here more than any other part of the body. The increased heart action points to a release of energy, and the blurring of the senses show that energy has been diverted and changed from its normal channel.

In many cases alcohol is used up to the toxic limit of full narcotism. Then a period of abstinence follows. After a time these cases become periodic, and the drink-storm occurs with regular or irregular intervals. The exciting causes of the return of the paroxysm are complex and uncertain. Each paroxysm is longer, more intense and followed by greater prostration. The first glass of spirits seems to both liberate and concentrate nerve energy in a convulsive demand for more spirits until narcotism comes, and even then the demand continues long after the capacity to retain it has passed away. This convulsive discharge of nerve energy as in epilepsy becomes a disease of the central nerve centers. Like epilepsy, it may continue for years before ending in death.

Alcohol may act as an exciting cause, exploding and concentrating unstable elements of nerve force, rous-

ing up latent predispositions and precipitating degenerations. Periodic convulsive drinking belongs to the family of epilepsies, and has many symptoms in common. They are both central nerve diseases and follow a uniform course to the same end.

General paralysis is another disease which dates from the use of alcohol. In nearly all cases alcohol is used to excess at some time in the progress of the case. It is a symptom as well as a cause, and it is often difficult to separate one from the other. Pneumonia, nephritis, cirrhosis and other acute organic diseases follow the use of alcohol, and are the natural sequel of acute degenerations.

It is not possible at present to specify any particular diseases which are caused by the action of alcohol alone. Like the poison of syphilis, alcohol seems capable of producing the most complex degenerations in every organ and tissue of the body. It not only brings new abnormal force to the brain centers, but deranges and perverts that which exists. Pathologically the injury seems widespread and general, affecting cell and tissue alike, both retarding nutritive cell growth and waste elimination; physiologically deranging the functions of the organs and then the structure, diminishing their normal activity and capacity. Psychologically it effects the higher brain centers, with a literal general paralysis going on down to the lower centers and functions following a graded line of dissolution. Structural injuries of the peripheral nerves, which comes directly from alcohol, are common. In chronic cases these injuries are well recognized, but in moderate and periodic drinkers they are overlooked. They are called rheumatism and neuralgia in cases where the cause of alcohol is not prominent. I have found these lesions in persons who have abandoned the use of alcohol or have long free intervals of sobriety. The injury from alcohol, which begins as interstitial inflammation, becomes a parenchymatous degeneration, and is confined to the sensory nerves first, and the brain later.

Ataxia and loss of muscular power comes on in the later stages.

Alcohol seems to have a special toxic action over the peripheral nerves. Arsenic and other minerals have a like power, and we are able to differentiate a number of different forms of neuritis.

Alcohol as a factor in diseases has two very pronounced actions. One on the dynamics of nerve force and the other on the nutrition and source of supply and energy. The nerves are over-excited and depressed and then activity is perverted, and the power of restoration from nutrition destroyed. The two central processes of life, waste and repair, are affected, one increased and the other diminished. These facts seem to be sustained by a great variety of evidence which admits of no other interpretation.

In clinical studies of cases the inebriate, or the person who uses alcohol in so-called moderation, may not exhibit symptoms of well marked disease, or of diseases which are described and classified in the textbooks, and yet the evidence of exhaustion, degeneration and general derangement is always present. There is present in these cases a profound lowering of nerve energy and vigor, associated with a prodigality of waste and delusions of strength that is not apparent to superficial observation.

The apparent recovery from the narcotism of single drunk paroxysm is never real. The convulsive discharge of nerve energy through the actions of alcohol

permanently derange the dynamic equilibrium of the nerve centers. Its repetition fixes this condition, and the power of resistance to disease becomes less. Local inflammation from infectious agents, from injuries, strains and drains, can not be overcome and death follows. Alcohol has been the factor which made these conditions possible, and destroyed the *vis medica nature*.

In this general outline of the facts concerning the power of alcohol as a factor in central nerve disease, the following facts may be restated:

1. Alcohol is a poison of the narcotic class, with a special tendency to act on the brain and nervous system.

2. In a general way the effects of alcohol are the same. Disturbing the functional processes and diminishing the sensory activities, ending in general muscular depression and mental enfeeblement.

3. A general psychical paralysis beginning with the *ego* and extending to all parts of the body, varying in some slight degree, but marked in all cases.

4. In dynamics of the brain there is a continuous gathering and discharge of nerve energy. This is increased, retarded and perverted by drugs, foods and environments.

5. The change of this nerve energy is seen in the functional disturbances of the body. In early and late life it is very prominent.

6. Alcohol produces marked functional derangements. It both releases and concentrates nerve energy. The increased and diminished vascular actions, with diminished sensory power, point to profound disturbances of the dynamic forces of the brain.

7. Periodic drinking is a convulsive disease like epilepsy, and is of the same family group. General paralysis is another similar disease, associated with exhaustion.

8. Alcohol acts on the body psychologically, physiologically and pathologically, and is a literal paralysis and dissolution.

9. No other substance known in common use has such a profound destructive action on waste and repair of the body.

10. This opens the door for many diseases by destroying the power of resistance and enfeebling all the powers of life.

INEBRIETY AND TUBERCULOSIS, ALLIED DISEASES.

Presented to the Section on Neurology and Medical Jurisprudence at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY T. D. CROTHERS, M.D.

SUPERINTENDENT WALNUT LODGE HOSPITAL,
HARTFORD, CONN.

The very close relationship between these diseases has been noticed for many years.

In certain families, tuberculosis and inebriety alternate. Some of the members will drink to great excess, then abstain, contract tuberculosis and die. Others will have all the symptoms of tuberculosis, begin to drink and recover from the consumption, become inebriates and die suddenly of acute pneumonia or nephritis. It is very commonly observed that inebriates who abstain from all use of spirits, calling themselves cured or reformed, soon contract tuberculosis and die. Such cases are very acute and rapid in their progress and termination. Another fact never understood was the apparently abortive influence of

alcohol in early stages of tuberculosis. The old-time prescription to drink all the spirits possible when lesions of the lungs were made out, always ended either in precipitating the disease to more rapid death or a low form of dementia and inebriety. The latter was always associated with delirium and exhaustion, and terminated in some acute disease.

The following case represents a class which will disappear in the near future when this subject is better understood:

A., aged 22, had incipient phthisis; he was given at regular intervals large quantities of whisky, and a year later recovered, but continued to use spirits. For the next five years he drank continuously and became demented. He was placed in an asylum and recovered; this was followed by bronchitis and fears of returning phthisis, and he returned to the use of alcohol. He is now a low imbecile inebriate. The frequency with which these diseases appear associated and following each other are attested by all students of inebriety.

In my experience with 2000 cases, fully 20 per cent. are associated with tuberculosis. I believe a much larger percentage of all cases of inebriety die finally from tuberculosis, of which probably there was no intimation until at the end of life. These associated cases have a common heredity and a great variety of common symptoms, which are apparent to all close observers. Dr. Maudsley, in "Pathology of the Mind," has described a class of cases which inherit qualities of mind and body that end in both tuberculosis and insanity. They are called phthisical insanities, and although they have no signs of tuberculous deposits or insanity, there is present a peculiar predisposition, which quickly merges into the one or the other from the slightest causes. These symptoms are marked in a large number of inebriates before inebriety is developed, and are of the same family type and identical in many ways. Such persons possess an intensely active nervous organization. They are quick, irritable, passionate, fanciful and changeable, eager in project and impatient of opposing delays, very idealistic and unstable of purpose, brilliant in flashes, but always wanting in breadth and calm depth of thought and in methodical steady perseverance. They are always quick in thought and intense in their energy; seeing the project of the hour they press toward its realization as the only important thing in the world. In a brief time they turn to some other scheme and abandon the first. In all they do there is the same futility of energy and display of imagination, with hectic credulity and irregularity of thoughts, feelings and actions. There is another class, more of the imbecile type; they are dull, heavy, impetuous and unreasoning, with little or no self-control, usually gormandizing and have no other pleasure than to gratify the impulses of the moment; usually have marks of defective growth and degeneration, and sometimes are prominent in business enterprises and show much activity of mind and body. In both of these classes inebriety, insanity and tuberculosis are almost certain to appear alternating one with the other. They are hereditaries of the same class, states of defective and retarded growths, followed by exhaustion and low vitality. The ancestors of these persons were very largely inebriates, insane and tuberculous.

Insanity is not so frequent, and seems to depend on some peculiar exciting causes which can be traced, such as injury, sunstroke and some peculiar mental strain.

Inebriety is simply narcotism to remove the pain and suffering from the defective functional activities.

Heredity has left the person with low and defective vitality, with feeble power of resistance and inability to adjust himself to the changing surroundings. He is in a state of chronic exhaustion, continually using up nerve energy that is replaced with great difficulty. His defective brain is unable to conserve force and hold it in reserve for emergency. Hence the seductive relief which comes from the narcotism of alcohol. Inebriety is only a symptom of this central bankruptcy of energy and power to develop force for the functional activities of life. The same conditions of weakness and degenerations diminish the power of resistance to the attacks of microbes and tuberculosis. Also the same conditions make the narcotism of alcohol fascinating and create the impression of strength by concealing the physical pain and demands for relief. In the latter case the degenerations go on, more profoundly effecting the higher centers with sensory hallucinations and delusions and changing the metabolism of the body. While alcohol apparently checks the invasion of the microbes and changes the symptoms, it creates new centers of degeneration and destroys the powers of resistance to every condition of strain and drain on the body. The removal of alcohol rouses the predisposition and favoring conditions of the soil for the growth of the bacillus.

If the degeneration has not taken on acute forms in other centers as in inflammation, tuberculosis may follow. A great variety of facts attest these observations and suggest a wide field for more exhaustive studies. One of these facts shows that families of inebriates and consumptives are often very fecund and numerous. Where the degeneration of the parents is unmistakable, the number of children born are often very large, confirming the oft noted fact, that just before the final extinction of the race a supreme effort is made to perpetuate the seed and save it from final extinction. The oak tree about to die will be over-burdened with acorns. The mongrel dog, whose race is nearly run out, will have an unusually large litter of puppies, which will die in infancy. While the families of inebriates are often very large they do not live long. If they live through childhood, they carry with them into maturity defects which soon end in extinction. Two degenerate members of a famous family in New York married. Both were moderate drinkers. Of the thirteen children born five died in infancy and eight grew to maturity. Three of this number died of tuberculosis, and were inebriates, one succumbed to acute pneumonia, one became demented, two died of some low form of fever associated with rheumatism. One is still living, but is feeble-minded, and has been eccentric and partially demented all his life. All the descendants of these persons are dead.

Another typical illustration of this class came under my care. Three members of a family of nine came for treatment for inebriety. One relapsed and became insane; the second was killed by accident; the third is a low drunkard; two of the remaining children have died of tuberculosis; one is an eccentric reformer with extreme zeal and little wisdom; one is a paranoiac single woman. The parents of these children were wealthy, drinking persons, without business, who died in middle life from some acute disease.

These dying families are by no means uncommon, especially in the older sections of the country. They

appear in the two extremes of either great fecundity or barrenness. In one case a sudden large progeny will follow, in the other barrenness, and in both profound constitutional diseases appear with tuberculosis, inebriety and insanity in its obscure and modified forms. Where a general history indicates that the family is degenerating, growing weaker in appearance and conduct retrograding, tuberculosis and inebriety with hysteria, eccentricity, rheumatism, and a variety of nerve disorders are almost certain to follow. Inebriety and various forms of drug addictions come first, then tuberculosis or acute affections such as pneumonia, hepatitis, nephritis and affections of the heart. These facts are not observed carefully because often the person or victim manifests some unusual form of vigor and ability before these diseases appear. A son of one of these dying families took high honors at college and entered professional life with brilliant prospects. He attained eminence, suddenly became an inebriate and two years later died of tuberculosis. His inherited degeneration was overlooked in his precocious brilliancy, and display of vigor masked the early dissolution which concentrated in inebriety and tuberculosis. Not all these cases become tuberculous or inebriates; other organic affections appear. The heart and kidneys suffer with the stomach, and a great variety of nervous affections which are likely to concentrate on the lungs, or depress the nerve centers to such a degree as to demand narcotics for relief. This sudden or gradual lowering of the co-ordinating nerve centers in vigor and power may be felt first in the lungs, and then the microbe's soil is ready for the growth of tuberculosis. The inheritance of low vitality and a predisposition to seek relief in spirits and drugs that cover up and relieve this pain and physical unrest, still farther lowers the nerve centers of co-ordination, literally enfeebling the power of resistance to all microbial invasions, and making the possibility of tuberculosis more certain.

The neurotic origin of tuberculosis has been for many years urged by Dr. Mays of Philadelphia, in many able studies. He has shown conclusively that tuberculosis is far more common in feeble-minded neurotic families. He has proven that it follows more frequently in families of inebriates and those who are eccentric, hysteric and possess a neuro-psychopathic constitution. These facts are not new but have been observed by many competent authorities for years. Dr. Mays has restated them with much additional evidence and many new conclusions that are unquestionable, proving the neurotic origin of consumption.

The present great precautions used to prevent the transmission of tuberculosis germs overlook this fact. The common neurotic origin of tuberculosis and inebriety is also noted in the paroxysmal character of their progress and termination. Cases of tuberculosis come on suddenly, pass rapidly to a fatal termination, or are marked by long irregular halts and apparent recoveries, which are supposed to be due to certain remedies or means used. These halts are paroxysmal, irregular and followed by other diseases or death from the original disease. Climate cures, drug cures, food cures, are all secondary to nerve rest and hygienic measures which build up the brain and central nervous system.

Inebriety begins the same way, in many cases suddenly, and is followed by halts and paroxysmal changes. Then the drink crave breaks out again, subsides, then changes to acute inflammation of the lungs or kidneys.

A period of moderate drinking seems to prepare the nervous system for drink-storms and excesses.

In tuberculosis, bronchial catarrhs and irritations of the throat, lead up in the same way to pronounced tuberculosis. In many cases of tuberculosis a marked mania exists for drugs of some kind. This is the same craving for relief that possesses the inebriate. The former is filled with the hope of virtue in drugs, is credulous, expectant, ever ready to try every new thing, never doubting its possible good effects. Filled with delusions of strength and final cure of his malady, the inebriate has the same boundless confidence in his power to abstain and ability to use spirits at all times and recover from the effects. The similarity of these cases can be traced in a great variety of symptoms which are identical in both cases. In both of these diseases there are similar nerve degenerations which may concentrate on any organ of the body.

Dr. Alison, in an exhaustive paper on the etiology of cirrhosis and pulmonary phthisis among inebriates, found phthisis more common among those of active habits.

He studied eighteen inebriates in fifty-four cases of phthisis, and asserted (*Archives Générales de Médecine*, Paris), as his positive conclusion that the use of alcohol predisposed to consumption by lowering the powers of nerve resistance, and by creating a constant source of irritation in the bronchi and lungs from the elimination of the alcohol. He was also clear in his conviction that inebriety and consumption were interchangeable, one following the other from the same general causes and both more likely to occur before 40. After that, acute inflammations followed more readily.

Dr. Mays, in the *Journal of Inebriety* for 1889, reported a number of cases from German authorities where death occurred from some form of inebriety, and the postmortem revealed tuberculosis and lung degeneration. In the same paper he reports a number of cases of inebriety following in the children of consumptives, and of phthisis or consumption appearing in children of inebriate parents. Dr. Haycraft, in "Darwinism and Race Progress," declares that criminals, inebriates, lunatics and consumptives, are all born with neuro-psychopathic constitutions, and in no other affection does heredity play so important a part.

Dr. Irwell, in "Racial Deterioration," describes the neuro-psychopathic constitution as a permanent condition of defect and weakness of the psychical nerve centers, noted in instability of nerve and brain power, lack of persistency, headaches, insomnia, indigestion, great susceptibility to environments, exaggerated emotional activities and a general insane temperament.

Dr. Williams, in his work on pulmonary consumption, written some years ago, describes the close relation between inebriety and consumption, calling them members of the same family group of diseases, one alternating with the other.

The fact has been noted by many specialists that inebriety often terminates in acute inflammation of the lungs and kidneys, coming on suddenly, showing that exhaustion has a special tendency to concentrate in this way.

Dr. Clouston of Edinburgh, in a late report says, that it is surprising how often insanity, consumption and inebriety appear in the same family and follow down to extinction among the descendants.

When one of these diseases is present the others are most likely to follow. Dr. Payne, in his "Pathology

of Chronic Alcoholism" says: "I can find no evidence to support the opinion that the free use of alcohol checks the progress of tuberculosis." On the contrary, the impression seems well founded and firmly held by many authorities that inebriety follows tuberculosis, and that they alternate one with the other frequently; at least there can be no question that they are very frequently associated.

Dr. Sharkey, in the London Pathological Society, claims that disturbances and lesions of the vagus nerve by lowering the nutrition of the lung, predispose it to become the nidus of the bacillus of tuberculosis. Hence all inebriates are predisposed to tuberculosis, and are more likely to contract this disease than any others.

The evidence of the neurotic origin of tuberculosis is often overlooked in bacterial study. The same extraordinary care to prevent infection in public places should extend farther back to heredity, alcohol and the great strains and drains that lower the vigor and lessen the power of resistance and make it possible for bacteria to find favorable soil for the destruction of the body.

THE INFLUENCE OF HYPNOTIC SUGGESTION UPON PHYSIOLOGIC PROCESSES.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY R. OSGOOD MASON, A.M., M.D.
NEW YORK, N. Y.

That hypnotism is a fact, and that the power of suggestion is marvelously increased while the patient or subject is in the hypnotic condition, are now truisms to all who have been students in that domain of psychology to which these subjects belong. The old rubbish of superstition, supernaturalism, and even of occultism, is in part at least swept away, and these two facts now stand out clear and distinct. It remains, by observation and experiment, to test their possibilities and ascertain to some degree the limit of their influence and usefulness.

Permit me to remark regarding the general drift of therapeutic practice in nervous diseases no less than in other departments of clinical work, that notwithstanding the tendency to specialization, and the multiplication of remedies in each special department, still amongst the wisest and most conservative in all directions the tendency is toward moderation and simplicity in the use of remedies; and thought is given especially to the repair of organs through physiologic processes, rather than the search for authoritatively endorsed specifics. Nothing can better illustrate my meaning than the treatment of epilepsy during the past thirty or forty years; there were first the salts of silver, then the salts of zinc, then the bromid of potash, and then that remarkable shot-gun invented by Brown-Séquard, in which all the known bromids were combined; later the bromid of sodium alone was the favorite, and now the general feeling is that in the ultimate results bromids are harmful, and that diet, regimen, air, and regulated exercise are much the most important factors in the treatment of this formidable disease. In other words, attention is being directed from specifics to the consideration of what can best be done for the repair and healthy action of damaged nerve cells and imperfectly functioning organs.

I am aware that there is a very decided feeling in the profession that the uses of hypnotism and suggestion are extremely limited, and that a few nervous or imaginary diseases constitute their main field of utility. Let us inquire whether this impression is well founded; and as a single but most important department of that inquiry and one harmonizing well with the general trend of medical thought and practice, I will direct attention to the influence of hypnotic suggestion upon physiologic processes.

In studying this subject, as in all others claiming a scientific basis, the first thing is to present the facts. An abundance could be cited from well known and reputable authorities; I will, however, confine myself to those which have come under my own observation. I will briefly describe a few cases where physiologic processes have undoubtedly been so influenced.

1. The influence of suggestion upon the action of the stomach. M. M. was a public singer, and near the end of a New York season was thoroughly worn out and exhausted. Food was absolutely distasteful to her, and if taken was seldom digested, but generally vomited, and as might be expected under such circumstances, her voice had failed seriously. She was brought to me to see whether hypnotism could afford her any help. She proved an excellent subject and was put promptly into the deep sleep. I suggested that she would at once have a strong desire for food, would be able to take it freely, retain it and digest it perfectly; that her strength and vitality would, as a consequence, quickly return and that night there would be such an improvement in her voice and singing that it would be the subject of general remark, and that her friends would congratulate her.

Her midday meal occurred directly after leaving my office, and her friends were amazed at the food which she ate with enjoyment. It was retained and digested, her strength and vitality were at once improved, and the improvement in her voice and singing was actually, on that same evening, the subject of favorable comment. Two more treatments carried her through her engagement with comfort and credit.

2. The influence of suggestion on the function of the lower bowel. Miss A. was a bright, intelligent educated German, 26 years of age, free from any hysterical or unusual nervous symptoms. She was the subject of obstinate constipation, and seldom had a movement from the bowels without medicines or enemata, often going unrelieved four or five days, and it was then with difficulty that even partial relief was secured. She was easily hypnotized, and one evening, while in the hypnotic condition, was given a single teaspoonful of pure water, with the suggestion that it was a bitter dose but very powerful, and that it would give her a perfectly free and full evacuation at 7 o'clock the following morning. She took the water with many grimaces at its bitter taste, and the suggestion was realized with such promptness and energy as to awaken her suddenly from sleep at exactly 7 o'clock, and to be the occasion of serious inconvenience.

3. Its influence on the menstrual function. Miss F., 18 years of age, menstruated at 15 and was a fully developed and usually healthy girl. She consulted me on account of the absence of the menstrual flow, which had not appeared during the previous six months; she was, at the time, pale and anemic. She was put into the condition of light sleep, during

which I suggested improved digestion and assimilation of food, causing the production of a richer blood and a better nutrition; also that her menstrual flow would occur at its proper date, two weeks from that time. I ordered her to continue asleep one hour and then awake. The same treatment was given twice more at intervals of four days. At the time suggested the menstrual flow returned; her health was improved and the improvement was permanent.

4. Its influence on lactation. Mrs. H. was a young mother, primipara. Her infant was two weeks old, and notwithstanding care had been intelligently given to secure a proper supply of milk, scarcely a drop appeared, and the child had to depend entirely on artificial feeding. The mother was anxious to nurse her baby and I proposed hypnotism. She proved a fairly good subject and went easily into a condition of light sleep, in which I suggested that the organs for supplying milk were perfect, and only needed stimulating to proper action; that at 1 P.M., it being then 11 A.M. she would take her bowl of hot gruel, and at 2 P.M. she would feel the milk coming freely into her breasts and that there would be an abundance for the baby. The suggestion was exactly fulfilled in every particular, and at 2 P.M. the babe had a full and satisfying meal from the mother's breasts, and artificial feeding was discontinued.

5. Its influence upon absorption. Mrs. X., 26 years of age, had been an invalid four years. Her condition was the result of pelvic cellulitis following a miscarriage. The right broad ligament and ovary were still involved: were greatly thickened by plastic deposit and very tender and painful on bimanual manipulation. Her menstruation was excessive in quantity, lasting seven or eight days, and was accompanied by large clots which were expelled with great pain. She was a complete invalid, constantly under the doctor's care, and though of an unusually active temperament was obliged to spend weeks at a time in bed. She was thin in flesh, badly nourished, nervous and anemic. A competent and conservative gynecologist had advised the immediate removal of the ovary as the only hope for improvement. Three days later she consulted me, and I advised delay, with the expectation that great improvement would speedily occur as the result of treatment.

She proved an excellent subject, and I suggested first, ability to take food, improved nutrition and the disappearance of pain and discomfort from the pelvic region; and these suggestions were promptly realized. Then followed the suggestion that the process of absorption would be stimulated and the adventitious deposit, from the old inflammatory process would be gradually taken up and removed; that the congestion of the uterus and pelvic viscera generally would be relieved, and that the circulation through these organs would be unobstructed. Then that menstruation, when it occurred, would be normal in quantity and free from clots and pain. This was eight months ago. Improvement commenced immediately in her nutrition with relief from pain; then followed a more normal flow at the menstrual periods; the thickening and tenderness of the adnexa of the uterus upon the right side were distinctly diminished and today very little difference can be detected in the two sides; menstruation is normal and painless. Very slight tenderness of the ovary of that side can be detected on bimanual manipulation, but her general health is good. She is well nourished, of good color, cheerful and hopeful.

It will be noted that the suggestions were not all made at once, but successively, as her condition demanded, and always with a distinct appreciation of the physiologic processes which should be stimulated or controlled in order to bring about the desired result. In making the suggestions it was not sought to use language adapted to the comprehension of the patient in her normal condition, and that used was never heard by her or at least never became a part of her usual consciousness.

I will not give a needless detail of cases, though they could easily be multiplied. I simply wish to call attention to the fact that in a great variety of cases and a multitude of instances physiologic processes have been influenced and controlled by suggestion.

Numerous cases have been reported by Liébault, Bernheim, Leigois, Dumontpallier, Burru, Kraft-Ebing and many others, where suggestion has produced changes in the physiologic processes of the body; changes in the heart's action, in temperature, in the vascular and vasomotor systems, causing the raising of blisters, bleeding from the nose or oozing of blood from designated points upon the surface of the body, and increasing or diminishing the various secretions of the body. With the knowledge of such facts before us, stigmatization, the reported cases of which now exceed 100, ranging from St. Francis of Assisi in the thirteenth century to Louise Lateau at the present time, becomes credible, and may be studied with interest and profit, and without loss of caste, even by persons of rigorous scientific orthodoxy. In fact, the old adage, "There is nothing that makes a man suspect, more than to know little," is most applicable to the matters here presented.

The field then in which hypnotism and suggestion are effective and may be made useful is not limited to nervous or imaginary diseases, but extends to a large class of functional disorders, and in some cases at least, and under some favorable circumstances, to serious organic disease; and the assistance rendered by suggestion in these cases is perfectly natural and scientific, and is due to its influence upon physiologic processes, stimulating, retarding and regulating with a certainty and success, varying according to the susceptibility of the patient and the knowledge and skill of the physician.

HYPNOTISM IN THE TREATMENT OF DISEASE.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY U. O. B. WINGATE, M.D., M.M.S.S.

Professor of Diseases of the Nervous System, Wisconsin College of Physicians and Surgeons, Visiting Physician to St. Mary's Hospital, Consultant in Neurology, Presbyterian Hospital, etc.

MILWAUKEE, WIS.

From the earliest period in the history of the healing art, there has always been a strong tendency to accept any mysterious or unknown agency in the treatment of disease; more especially is this acceptance favored by the less learned in science, and among those afflicted there is always found a large clientage who are ready to be operated on by anything surrounded by mystery or pertaining in any way to the occult.

Hypnotism, undoubtedly, owes to the mysticism

that surrounds it its existence and practice. If it were better understood, no doubt it would be neglected and soon forgotten with the host of other agencies that have existed in the past and lost their charm as they became understood.

To the scientific physician it fails to create confidence enough to be of much use, and its employment is now apparently largely in the hands of that class of practitioners who seem to play on the credulity of the public more than to treat disease in a strictly scientific manner. I am well aware that I am open to severe criticism by some, but I base my statements upon my own experience and observation. With a large acquaintance with practicing members of my profession, I have failed to find but few who care to make use of hypnotism as an agency in their practice, and those who do use it appear to do so more as an experiment than as honest scientific treatment. In the use of it myself I have always felt some degree of guilt, and am sure I could have accomplished similar results with agents that are more scientific, more satisfactory, and with a feeling that I have not left behind conditions that may be harmful, for I am sure that the results of the use of hypnotism, in many instances, may be harmful.

If the nature of hypnotism be such as Maudsley describes, and I see no good reason to doubt his conclusions, surely we should think long and carefully before employing it in our practice. He says:

"What may we suppose to take place when a person is thrown into such a trance in which, machine-like, he is governed by suggestions which the operator makes, touching, tasting, seeing, hearing, thinking and doing just as he is bid? That by the special suggestions made, the fit tracts of his brain are stimulated to a separate and pretty nigh exhaustive activity, while the functions of the remaining tracts are suspended. Thereupon he can not choose but perceive as he has been made to think; must translate every impression on sense into the language of the solely active idea, and shape to its features, or else have no consciousness of it at all. He can not possibly perceive in the terms of ideas that are entirely inactive. The one active cerebral tract is virtually the whole and sole mind which he then has, and to obey it in sense and act is a compulsive necessity. For the time being he is effectually severed from full mental contact with things as if he had been educated through life to exercise that tract and none other, or as if he were a madman, dominated by its morbid growth and function. There is good reason then, why persons of weak and unstable nervous temperaments can, while persons of strong, compact mental organism can not, be thus put out of possession of themselves, and why those who have frequently allowed their mental being to be thus dislocated become so unstable, at least as to fall out of mental joint at the least suggestion. Nay more, there are persons who under enthusiasm, or other mental excitement, can perform a self-hypnotism, and afterward so cultivate the acquired function by strain and practice, as to repeat the operation at will, with the greatest ease." Such is the character of this agency, which no doubt has existed as long as the history of the treatment of disease varying in degree of potency in different ages and under different conditions of the human family.

That we are living in an age where from the activity and strife and strain of life, in a severe struggle for position and existence, coupled with a heredity that is becoming more and more conspicuous, when there is

great weakness of the human mind and tendency to nerve deterioration and mental decay, no one who carefully studies the events of the times can fail to observe. This condition produces a large train of human minds that crave leadership, in other words, minds easily influenced by suggestion; hence we see hypnotism more easily practiced than in some other periods in our history. Human credulity seems to be at its highest point, the great masses of the people are capable of being easily led by the suggestions of the few, and such a condition can not be considered as a healthy one in the body politic. If it be true that by the practice of this agency, we weaken the subjective mind instead of giving it strength, if by repeated suggestions it becomes more and more easily affected, and dependent, surely such treatment can not be of advantage to the subject, but on the other hand, we are increasing the weakness of the will of the individual, and surely in this direction madness and mental decay lie.

To quote again from Maudsley, relative to hypnotism: "The compact consciousness of the supreme centers has become broken up, a discordant tendency fostered, and the disassociated centers are prone to continue their abnormal and independent action. This state frequently follows too oft repeated hypnotic experiments in the same individual, and assuredly that way madness lies."

Charcot said nothing of the therapeutic uses of hypnotism. He indeed pointed out that a woman who had hysterical paralysis of one leg, walked about and seemed cured during hypnosis, and that though he might temporarily remove the paralysis by suggesting its disappearance, that such a remedy did not treat the disease she labored under, but only allayed one symptom. He treated his cases of hysteria according to the best principles known, namely, seclusion, fattening foods, and the physiologic mode of living.

Dr. Robertson states that it is the general opinion of the medical profession in Nancy that while hypnotism has done some good, in many instances its general affect is more harmful than beneficial, inasmuch as the general belief by people in occult powers, and the power of one man's mind over the conduct of others weakens will power and thus becomes injurious.

There is no doubt but that outrage can be effected in the hypnotic condition, and although it may be doubted if crime can be committed, it seems that the weight of evidence is largely in that direction.

All writers on the subject condemn public exhibitions of this practice, and I believe the time will soon come when its use by the medical profession will entirely give way, as I believe it should, to safer and more scientific methods of practice, and by other therapeutic agents.

204 Biddle Street.

DISCUSSION ON PAPERS OF DRS. MASON AND WINGATE.

Dr. T. D. CROTHERS—Suggestion is a physiologic, and not a pathologic process. I believe it is more absolutely certain than Rochelle salts or any other medicine that we are in the habit of using. I know that no man can practice medicine without suggestion; you may call it personality, or magnetism, or may attempt to define it, but in reality it is suggestion.

Dr. TWITCHELL—In the last few months I have written 100 letters to leading psychologists, both in this country and in Europe, and have received 41 answers, only 2 of which were opposed, not only to the use, but to a better teaching of this subject in our medical colleges. Solomon Solis-Cohen of this city wrote that he believed in an all-round study of the mental faculty both in disease and in its cure. I believe the time is coming when, not only will every physician throughout the land recognize this factor in treatment, but it will be taught

in all our medical colleges. As to the injury done by hypnotism, how many of us are absolutely certain that any of our drugs does not produce evil effects? How many of us will use morphia, or any potent drug, and feel absolutely certain that in any given case he will produce no injury?

Dr. MOYER—I do not see the great dangers to be apprehended from hypnotism, and I suspect that suggestion, which I think is really what is understood by hypnotism, has been used almost from time immemorial, and that it explains a vast deal of the phenomena in the nervous system in disease which is not explicable on any other theory. It is only of late that I have been employing hypnotism at all extensively, and it is almost routine practice with me to hypnotize about all the patients that come to my clinic. I have yet to see any bad results. The number of cures that have been effected in this way is quite numerous. I can recall one striking case of hysterical paraplegia in a man who was brought to my clinic with great difficulty, partly carried up the stairway, and before he left was able to walk down the stairway. Another, an hysterical hemiplegic who had not been employed for four years, has resumed his work after four treatments of hypnotic suggestion. Suggestion has a wider range than that. Even in organic affections the patient becomes more hopeful and confident, and his general condition improves.

Dr. MASON—I had supposed that all were accustomed to look upon hypnotism as a fact, and one which we are gradually learning to apply scientifically, by means of methods of observation and drawing conclusions. Any statements in regard to the physical effects of hypnotism upon the brain are purely hypothetic, and there are no facts upon which to base any statement of this kind. Of course, from continuous hypnotism of one subject we might possibly have uncomfortable effects, but this is true of almost any other therapeutic procedure. I have used hypnotism twenty years, commencing before Charcot and Bernheim, and in all that time I have never seen an untoward effect of any sort whatever. Charcot endorsed hypnotism, and made use of it.

Dr. WINGATE—I do not understand that hypnotism is suggestion in the true sense. I believe that everyone uses suggestion; but when you render a patient unconscious, put him into the true hypnotic condition, then you make an impression upon him of an entirely different character. There is always a class of patients with whom this is repeated over and over again. We hypnotize certain patients continuously because we find it easy to do so, and I maintain that that constant brain action is injurious. I believe that hypnotism will in time injure the patient, and will not accomplish the good that is hoped for and expected.

A STUDY OF THE STIGMATA OF DEGENERACY AMONG THE AMERICAN CRIMINAL YOUTH.

Presented to the Section on Neurology and Medical Jurisprudence at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, June 1-4, 1897.

BY EUGENE S. TALBOT, M.D., D.D.S.

CHICAGO, ILL.

The present contribution results from studies on young criminals made during 1895-96 at the State reformatories at Pontiac, Ill., and Elmira, New York. The investigation concerns especially the stigmata of the head and face. The stature and weight were noted, but other anthropometric data were not specially considered, as measurements had to be entrusted to others. It was therefore deemed advisable to avoid as far as possible elements of error concomitant on extensive detailed anthropometry. Only simple measurements easily obtained with accuracy were made. Inasmuch as facial and cranial development are, as a rule, most directly co-related with moral and intellectual evolution it was deemed natural that they should furnish sufficient data for discussion in an article of the present scope.

Since the inquiry dealt only with the physical stigmata of the head and face, the youngest inmates were, for obvious reasons (immature jaw and face development) excluded from consideration. The object of the inquiry was to determine the extent to which the

youthful criminal came from the ranks of the degenerate. The question whether a criminal type, distinct from other degenerate types exists, does not enter into the scope of this paper, and has not been considered. Besides the stigmata, age and race are included in the inquiry and discussion. Details as to parentage, heredity and antecedents would have been of interest, but could not be obtained with any accuracy. Certain data naturally lead to inference unnecessary to point out; for example, the predominance of the foreign born and those of foreign parentage, especially of certain nationalities.

The details as to those of foreign and native parentage mixed would have been of special interest for purposes of comparison. The mass of the youth examined came from the unskilled laboring class, and from the urban, as distinguished from the rural population. These facts are to be recognized when it is remembered that the two institutions are hundreds of miles apart and draw their population from differing communities. The two institutions have therefore been considered separately to eliminate elements of error. The total number examined was 414 at Pontiac, and 1018 at Elmira. The ages ranged between 15 and 30. The average at Pontiac was a little over 19 and 21 at Elmira. For purposes of comparison records were made as to weight and stature and these were tabulated according to age, nationality and color. Only three or four nationalities are represented sufficiently to be of value for statistical purposes. The others are given for the sake of completeness. The nationalities were tabulated by considering those of foreign parentage on both sides as foreigners and those with one American parent as native born. This was thought a better course than designating nationalities by places of birth. It was thought desirable to classify certain individuals by race rather than nationalities, but this was very difficult. The Jews, for example, in Pontiac are included among the Germans and Poles. Pontiac contained one full-blooded Indian, but many of the negro inmates had a considerable proportion of Indian blood. The negroes included all with an appreciable negro taint, but full blacks were in the minority. The two institutions differ in their constituents. Pontiac is more particularly a reform school and receives a larger number of misdemeanants, whom in New York are sent to Westchester, Rochester, etc., rather than to Elmira. From the tables it will be evident that an older class of cases is received at Elmira. In tabulating, only those inmates of Elmira of 30 years and under are included; in Pontiac, the oldest is 26. The first table gives data as to age, stature and weight in the two institutions. This table does not include the whole number examined since it was impracticable in a few cases to obtain weight and stature, while obvious stigmata could be easily tabulated.

The most striking fact shown by these tables is the inferiority in physique of the Elmira inmates, as compared with Pontiac. The latter compare very well with the average urban population and still more favorably in these particulars with the artisan class of the larger English towns.¹ This is due to the fact that the degenerates and less active unskilled artisans of European cities locate on the sea border, while the stronger seek the interior or the country. The more apathetic emigrants of both urban and rural European communities are dragged into the cities.

In considering the difference between the inmates of Elmira and Pontiac the fact should be remembered, that for several decades subsequent to 1850 New York State maintained the suicidal policy of having an establishment especially for emigrant defectives on Wards Island. At the end of five years residence the epileptic, hysteric, pauper, prostitute and semi-criminal classes were turned loose to drift into city institutions, or to remain in the city itself. The insane and idiotic were directly turned into the New York City institutions. The defectives less than five years resident in the United States were returned from other States to Wards Island, thus causing an undue accumulation of defectives in New York City. The mere existence of the Emigrant Refuge led to the settlement of the less energetic emigrants directly in New York City. The ordinary tendency of careless charity had its usual effect in increasing the defective population of New York City, and hence of increasing the number of defective youth.

The number at the younger age in Elmira is too few to be compared with the results of Bowditch, but so far as they go, compare favorably. The New York figures under-run Roberts' results at nearly all ages and in nearly all nationalities. The difference is more marked in weight than stature, while very apparent in the latter. The American figures indicate that the rush and roar of city life attract active degenerates from the country, the more apathetic urban degenerates remain in cities, while the more active press westward. In a general way, the comparison between Elmira and Pontiac tends to show that the more robust and restless of the degenerates as well as of the eastern rural population press westward. It is certain from the studies of the defective classes that apathetic defectives like paupers and prostitutes have less tendency to wander.² The more active defectives like the paranoiacs, periodical criminals, etc., have a tendency to wander. The influence of climate and soil has been too recently exerted to be demonstrable in the difference between New York and Illinois.

Table two shows the difference between the reformatories more strikingly than can be done by words alone. In it the average stature and weight, according to nationalities of inmates over 20 years of age, are given. This table includes the adult averages only. It is possible that the stigmata of lipomatosis has to be considered relative to the question of weight. The difference in weight between the two reformatories is particularly noticeable. The inmates of the eastern reformatory are generally a more slender type. In considering the question of lipomatosis the fact should be remembered that the cases admitting of this possibility are comparatively few, and the light individuals are much more numerous. The range in this particular is much more evident in Elmira than at Pontiac. As regards stature, the range was much greater at the latter place. It would be too strong a statement to claim the influence of western soil in this particular, as has been done by some criminal anthropologists. Data of comparison with the stature of the races are wanting.

The cephalic index is one of the most interesting of the anthropologic data. The results at both Pontiac and Elmira are summarized in table three. The marked dolichocephalic in both institutions is very noteworthy. As it contrasts with the marked mesocephaly of the populations from whence these crimi-

¹ Roberts' Manual of Anthropology.

² Eighth Annual Report, Massachusetts Board of Health.

nals are drawn it is clearly a stigma of degeneracy. This is true even of the negroes, since in 2,000 examinations I found but 6 instances of dolichocephaly in Chicago. The Irish in Pontiac, and the Germans in Elmira, appear to be the least dolichocephalic, though their average index is decidedly below the lowest mesocephaly. In a general way this result tends to confirm the opinion expressed as to the proclivity of the apathetic foreign degenerate to remain on the seaboard. It is notorious that the more active Irish of the rural class go eastward. The more apathetic of the Germans remain in the seaboard towns. In no case could there be said to have been notable exaggeration of the racial type. It is unfortunate, however, that the cranial index of the districts from which these populations were drawn could not be obtained. Both Ireland and Germany are stilled dotted with dolichocephalic colonies.³ The fourth table gives the breadth of the upper jaw measured from the outside of the first permanent molars and corresponding measurements from the second bicuspid. This will aid in giving an idea of facial proportions and average contours of the dental arches. The fifth table shows the variations in the height of the palatine vault. The width of the jaws between the molars and bicuspid of the four or five leading nationalities at Pontiac was decidedly in excess of the corresponding width at Elmira. This indicates that, notwithstanding the younger age, the face was wider and squarer than at the eastern institution. The Elmira measurements average less than those of normal individuals⁴ in the Eastern States. The Pontiac institution's average equals, or even exceeds the normal figure. By this fact the impression that the emigrant of better physique goes westward is confirmed. The height of the palatine vault averages a little higher at Elmira than at Pontiac. This fact, taking into consideration the importance that has been attributed to the height of the vault as a stigma of degeneracy is of decided interest. The difference however between the average of the two reformatories is too slight to be of much value, even were it certain that height of the vault had the importance attributed to it. As compared with what may be considered the normal vault,⁵ the average height in both Elmira and Pontiac may be considered under the normal, but much importance can not be attributed to the slight difference. The measurements of the width of the jaws, and of the height of the vault are, on the aggregate, of value, but their range above or below the normal not remarkable.

A series of measurements was taken between the eyes, measuring from center to center of the pupils, $2\frac{1}{2}$ inches being the average. More accurate figures would have been obtained had the measurements been made between the inner and outer canthi. The variations between the reformatories themselves and between them and normal communities are not very striking.

The more accepted stigmata of degeneracy present striking facts in these institutions. It is advisable first to establish a normal standard, remembering that the average individual possesses degenerative stigmata to a minor degree, and that only combination and excess in a number of these mark the degenerate in the higher sense of the term. To furnish a normal standard a series of persons representing the average

of the community was selected, and note taken of their stigmata, especially in the head and face. They were city residents of respectable standing, and were taken at random. The total number was forty-two; of these fifteen had subnormal, and seven excessive development of the occiput. Two had the bregma abnormally depressed; four had very low, and three receding foreheads; nineteen had an arrested, and seven excessive facial development; three had the nose sunken at alæ; twenty-six arrested, and three excessive, nasal development; one had the septum strongly deflected to the left; ten had abnormally small, and eleven very large orbital cavities, many of these also had the eyes sunken; four had V-shaped jaws; two partial V-, seven saddle-shaped and two semi-saddle-shaped jaws; six had irregular dentition: one hypertrophy, and one atrophy of alveoli; twelve had very large, and two abnormally small, development of the thyroid gland; not less than thirty-nine had one or more aural defects, either too large or too small, too widely or too closely set ears, adherent or excessive lobules, Darwin's tubercles, etc. Of the whole number there were only two with four stigmata each, one with five, six with six, seven with seven, six with eight, five with nine, four with ten, five with eleven, and four with twelve stigmata.

The average number of each individual was eight, and this may perhaps be accepted as approximately the normal figure, at least for the ordinary urban resident who does not belong to the defective classes.

Differences of opinion may arise in regard to the value of these defects as stigmata; yet, all elements of error considered, they furnish a fair method of comparison of the relative degeneracy of the respectable community and of the reformatory. Tables six and seven show that the stigmata of the average inmate of the reformatories are nearly double that of the average normal individual. In the New York institution the stigmata are double or more in nationalities of any number of those in the Illinois institution. The stigmata, hence, follow the same general rule as the physique. The inmates of the Illinois institution are noticeably less stigmatized by degeneracy than the New Yorkers. The native Americans of the New York institution presented an average of sixteen stigmata each. Those in Pontiac had only fourteen. While the difference was not so marked in the other nationalities, it was still sufficiently apparent. This corroborates the conclusion that the more defective degenerates remain on the sea border.

While stigmata other than those of the face, and head were not considered in the studies for this paper at any length still the majority of the inmates were found to present an abnormal proportion of them. Marked bodily asymmetries, disproportion of members, flat feet, were more common than in the average normal population. Though reformatory inmates are usually considered as somewhat distinct from the ordinary population of the penitentiary, they present many of its physical characteristics. In this connection some recent studies of Dr. Charles E. Woodruff of Fort Custer, Montana, which are to form the basis of a work on degeneracy in regard to military service, are in point. Dr. Woodruff⁶ remarks: "It is not often that criminals are enlisted, and the records, if gone over, will probably show that the number of crimes committed by soldiers is far less than those committed in any community among an equal number of young

³ Taylor, *Origin of the Aryans*.

⁴ *Etiology of Osseous Deformities*, 1894. ⁵ *Ibid.*, p. 74.

⁶ *Degeneration in Military Life*.

men. If a city has 20,000 young men, say of ages from 20 to 35, it is quite possible that it has over 200,000 inhabitants, and I know of no city of that size where there are so few thefts and serious crimes as in the army. This should have been expected from the exclusion of the worst degenerates by the physical examination. A large number of common stigmata unfit the person for military service, and as criminals were believed to be physically below normal, this I made a personal test to determine. Through the courtesy of Superintendent R. W. McClaughry, of the Illinois State Reformatory, I examined 138 young convicts, just as I would recruits. I excepted the hearing and eye-sight, as these tests are subjective, and their notoriously untruthful answers could not be accepted. As eye and ear affections are known to be quite common, there would have been more disability for these troubles had time permitted of examination by objective methods.

"They were divided into the following classes:

"1. There were only two in whom there was no discoverable defects, there were two others with very trivial defects, and ten more who would pass but might be rejected by a careful surgeon; total, fourteen.

"2. In this class were placed those having minor defects sufficient to reject an unknown recruit, but which the surgeon himself would feel justified in overlooking if the man were very desirable (a good mechanic, clerk, etc.), or in the case of re-enlistment; total, thirty.

"3. In this class were defects so serious that the surgeon would not feel justified in overlooking, but would recommend that special authority be asked to enlist the man if he were extremely useful or were needed for special service, not in the ranks, or were needed in war; total, thirty-seven.

"4. Defects which would exclude in peace times, but would permit of special service, clerk, messenger, etc., in time of war, thirty-three.

"5. Totally unfit either in peace or war for special or general service, twenty-four. Total, 138.

"Several very boyish, immature men, evidently too young, were not included, nor were negroes. It must be remembered that these are the best grades of criminals in whom the judge believed there was chance for reform. Some of them are normal men who have been in bad surroundings, that is, they were taught to be criminals. The physical defects of confirmed criminals in penitentiaries are more marked, and from a very imperfect and casual examination of those in Joliet prison, I believed that very few were capable of military service.

"Then, again, quite a large number of criminals cease their active careers as executors of crime at the age of 25, or thereabouts, and then become contrivers of crime directing others,—they are the capitalists of crime, running brothels, saloons, become "fences," etc. Therefore, at the age at which the majority of men enlist in the army, the criminal is too actively engaged to think of enlisting. When one does slide in by oversight, it is surprising how quickly the soldiers of his company take measures to get rid of him. In some years the recruiting officers reject as many as 90 per cent. of the candidates for enlistment, only 10 per cent. being found up to the proper standard. In that 90 per cent. will be found the worst degenerates. It is rare to have more than 25 per cent. accepted.

"It is reported that forty newsboys were taken to the Brooklyn Navy Yard to enlist, and that thirty-eight

were rejected as physically unfit. This is to be expected when we reflect that these boys are thrust into the street as a result of parental degeneration, and must be degenerates of bad type and of markedly inferior physique. We have already called attention to the large number of criminals who have hernia (over 10 per cent.), tubercular history (perhaps 50 per cent.), and heart disease (25 to 50 per cent.), shortness of stature, underweight, defective senses and intelligence, and a restlessness incompatible with military discipline. From all the above facts I would make a rough estimate that 95 per cent. of confirmed criminals are physically unfit for military service.

"Knock-knee and flat-foot have not usually been considered stigmata but deformities due to mechanical changes, and sometimes due to perverted development of the bones. The conditions usually go together, for it is rare to find flat feet in bow-legged men. Flat-foot and knock-knee are much more common among degenerates than is generally supposed. In the 141 criminals I examined in Pontiac, there were the following deformities of all grades:

	Per cent.
Feet and knees normal	67
Knock-knee alone	14
Flat-foot alone	34
Knock-knee and flat-foot combined	22
Very bow-legged	1
Bow-legged and flat-foot	3
141	100

"From the lack of resistance of degenerate structures one should be prepared to find, therefore, that more than half of these men should present anomalies of the feet and knees. I have very frequently been astonished at the high degree these deformities assumed in undesirable recruits. I kept no record of the number of the above cases in which the deformity was of sufficient grade of itself to unfit for military service.

"Ancient statuary is remarkable for the number of flat feet in which the arch is in various grades of destruction. Ancient models must have been very poor to cause the artists to copy this condition so often.

"As a mild form of knock-knee is a normal feminine characteristic, we find it well marked in cases of femininism. The mild grades of flattened feet in women are also in part normal, and follow quite naturally both from the normal knock-knee and the naturally weak tissues. Both conditions in males may then be a result of femininism. The infant's foot is normally flat, and so is the negro's, and its retention in adults may be atavistic. In the Elmira Reformatory, of 529 men examined, the arch of the foot appeared to be normal in 58.42 per cent., unnaturally low in 18.71 per cent., and flat in 22.87 per cent.

"Faulty position of the foot may be produced by an anomalous position of the ends of the long bones of the leg and thigh. The toes may be thrown far out, causing a shuffling gait, as though the man walked on his heels, or the toes may be turned in. In civilized man the feet make an angle of about 30 to 45 degrees but in many savages it is a smaller angle, or, indeed, the feet may be parallel.

"All the above states of the knees and feet must not be considered stigmata, as they are not always due to unstable development; but they must be given weight as indicating faulty developments of the tissues, a

degenerates, as, indeed, incidental research has shown. There have, however, been very few systematic studies of the younger criminal as a class, or of those who for various reasons have been found by judges better suited for reformatories than true penal establishments. The few examinations that have been made were generally of a more juvenile class than that here considered, and hence not well suited for the study of stigmata. The notes on the stigmata involved a greater number than are represented in the other tables. This, as has already been explained, was due to the measurements being made by others. There is no doubt however as to their substantial accuracy.

No attempt was made at systematic craniometric data, the chief aim of the observations having been to note the facial stigmata. In a general way, some more striking cranial deformities are noted; the excessive, or otherwise, occipital or bregmatic prominence, and the relative height of forehead. The most notable peculiarity in these respects is the large proportion of cases of pronounced height of the bregma,

more observable in the inmates of the New York State Reformatory than at Pontiac. While not pronounced enough in all cases to result in true oxycephaly, the tendency was in that direction. This fact is in accord with observations elsewhere on the criminal classes. The excess of development in the occipital region was likewise more common in the Elmira inmates, whose proportion of average normal heads was less than that of the western institution.

As regards the face, the tendency seems to be more commonly toward an arrested than an excessive development, especially at Pontiac, where a fairly normal facial contour is more common. The height or prominence of the zygoma claimed as a criminal feature was most common in Pontiac. There was no predominance of unusually large orbits (as described by Lombroso) in either place. A diminished orbital capacity was the rule, and in Elmira deep sunken eyes were in the majority. Nasal development of moderate degree was the exception at Elmira, but the rule at Pontiac. In the more particularly known mandibular deformities, the results were striking. Well formed or normal jaws were decidedly in the minority. The proportion of abnormalities (V-shaped, partial V-shaped, semi-V-shaped, saddle-shaped, partial saddle and semi-saddle) was excessive in both reformatories, (63 per cent. at Pontiac, and 60 at Elmira). These deformities, common in criminals, by the flaring out of the posterior portion of the lower jaw, contribute to the square lower face in the criminal physiognomy. The teeth were only in a moderate proportion affected by irregularities aside from those connected with deformities of the jaw. The same is true of alveolar

abnormalities. In both respects the inmates were fairly normal, and as regards regularity of dentition, were rather better than the average. The types of aural stigmata have been discussed in my paper on "The Degenerate Ear."

absence of an erupting or impacted third molar) in many cases does not furnish cause for the existing condition of the fauces. The patient has not applied to a laryngologist but to a dental, or oral surgeon, and it is his opportunity to put the mouth in a healthy condition; I think it is his duty to have suitable instruments so as to make a proper diagnosis, and either give proper treatment or direct the patient where he can receive the same. The venous stasis of the pillars acts as a sentinel, the etiology of which, if not in the erupting molar, will be found either in the tonsil or post nares. The tonsil may have little or no inflammatory action and the crypts may or may not be filled with a cheesy exudate, and still their sluggish condition will produce foul smelling secretions, and absorption by the lymphatics will follow. Also stenosis and chronic catarrhal conditions of the post nares will produce a dropping in the pharynx and keep the pillars bathed with a foul secretion which will taint the breath and produce, through absorption, an abnormal appearance of the pillars. Frequent attacks of coryza which do not receive treatment, and are allowed to become chronic, produce the same result and thus become etiologic factors.

The treatment consists in antiseptic gargles, of which borolyptol, either in full strength, or diluted, is one of the best; also an alkaline and antiseptic wash, as Do-bell's solution used as a gargle or spray for the throat, and spray for the nose. The tonsillar condition may be stimulated with nitrate of silver, grams 3.9 or 7.8 to aqua c.c. 30, or the electric cautery can be used to advantage. When the catarrhal conditions exist, any stenosis should be corrected, and the nares and fauces cleaned night and morning with an alkaline spray. In addition to this, two or three times a week, the iodine solution, grams 0.13 to 0.65 of iodine to the 30 c.c. of water with iodine of potassium and glycerin, will be found advantageous. I have found great satisfaction in the treatment of this affection as the condition is always improved, if not entirely cured.

TRACHEOTOMY IN DIPHTHERIA IN CON-JUNCTION WITH ANTITOXIN.

Read before the Missouri State Medical Association, May, 1897.

BY E. VON QUAST, M.D.

SURGEON TO GERMAN HOSPITAL AND HEALTH OFFICER,
KANSAS CITY, MO.

Of all diseases of childhood, laryngeal diphtheria or membranous croup is the most dreaded. Either the larynx is primarily the seat of affection or is secondary to tonsillar diphtheria. Sometimes the affection in both organs is simultaneous, or the post nares or tonsils have had a deposit which so rapidly spread to the larynx that the primary seat of infection was overlooked by parents until threatened asphyxiation called their attention to the fact that their darling was in danger and they sent post haste for medical aid. Whether the cause of membranous croup was identical with that of diphtheria or not, was for years a bone of contention in medical ranks. Volumes were written on the subject and differential diagnosis was a bugbear to the general practitioner. Gradually the profession became divided; one side believed in the duality of the disease and the other in the unity; and discussions *pro* and *con* were heard at meetings of medical societies in this and the old country. Infectiousness of true croup was doubted by a large and influential body of men, while others were firm be-

lievers in it, and only since bacteriology has thrown light on the subject and proven in the majority, if not in all, cases, the presence of the Klebs-Loeffler bacillus in the membranes and exudates, has the band of doubters been reduced to a very small body. It is to be hoped that soon the term "croup" and "membranous croup" will cease to exist in medical literature, cease to be posted in our cities as such, and cease to appear in our death reports; but simply be classified as diphtheria. Remedy after remedy for the treatment of membranous laryngitis was introduced, tried and extolled, but the death-rate remained enormous, even with tracheotomy, and soon it was condemned by a great number of the profession. O'Dwyer's tubes were hailed with delight by many operators, but even with their use the death-rate remained too high. This operation found more favor with the laity, while the profession used it more readily because the objections to the surgeon's knife were too great in many cases.

Intubation, universally used, failed to be the boon its champions claimed. Without discussing the merits or demerits of this operation, I will frankly state that I prefer tracheotomy as long as it gives the percentages of recoveries that I have had, both before and after the discovery and use of antitoxin in the treatment of this disease. Even before the introduction of antitoxin, my success in this operation was all that could be expected. It was not due to a selection of cases nor to a better understanding of the operation, but to the fact of its timely performance and the exercise of diligence in the after-attention and care of the patient. To do tracheotomy only as a *dernier ressort* is a grave mistake, for the vital forces of the child have been exhausted from the non-aeration of the blood. Still, I have met with success in two cases after sensation had ceased, by quickly opening the trachea and introducing a full sized tube, and performing artificial respiration. Breath and air is what is wanted at this critical moment. Minutes are hours and delay means death. Generally speaking the golden rule for performing tracheotomy is whenever dyspnea with cyanosis has manifested itself—the respiration murmur is faint or absent, with retraction of the chest wall, the attacks of extreme dyspnea becoming more frequent. Delay under such circumstances would be disastrous. The introduction of antitoxin into therapeutics marks a new era in the treatment of this affection.

In November, 1894, I read a paper on Antitoxin before the Jackson County Medical Society, by request, having closely followed the literature on the subject since 1890. A committee was appointed at the time, by the above named society, to investigate the use and action of the antitoxin, and a quantity was procured by the board of health. I was a member of this committee, and watched closely the effect of this remedy. At the end of a few months we gave a complete and unbiased report of our work. As usual with all new remedies, enthusiasm ran high in some quarters, while in others antitoxin was condemned as a fad and its use said to be dangerous. Now, after two years trial, enthusiasm has given way to sober judgment and it has received its place in therapeutics, has won friends and admirers in quarters where it was first bitterly opposed.

I believe that every unprejudiced physician must reach the positive conclusion that it is a valuable remedy and predict that the time will come when the

refusal to use this remedy in diphtheria in children will be regarded as criminal. It is to be regretted that it is not used by all physicians in these cases, and that there are still so many reports of death from membranous croup, where antitoxin, tracheotomy or intubation have not been used, children were allowed to suffer the horrible death of asphyxiation. Antitoxin is not a cure-all. Its early administration in membranous croup offers the best hopes of preventing the extension of infection, causes softening of the membrane and prevents septic infection. Frequently, indeed, it does away with the necessity of operative interference.

Reports from members of pediatric societies bear out the statement that, until the use of antitoxin, they had seen no case of recovery from membranous croup; and men of well known reputation have stated that by its use operations become less frequent. (O'Dwyer and Northup.)

A complete report of the New York Health Board shows that the mortality for operative cases has been reduced one-half as the result of serotherapy. To produce a satisfactory result in these instances, being the gravest of all forms of diphtheria, it must be given in very full doses. There is one great danger, however, in the loosening of membranes in large masses which are liable to obstruct the larynx or trachea and produce sudden asphyxiation. On this account the physician must not leave his patient until he is sure the membranes have come away, respiration is restored to a normal condition, and all signs of obstruction and cyanosis have passed away. If no improvement follows, no air enters the lungs, and thoracic breathing continues with a dusky or very pale countenance and a slow, weak pulse, it is better to do a tracheotomy at once than to wait for possible relief. By following this rule, I have, within the last ten months, performed five successive tracheotomies without a single death. The youngest of these children was $3\frac{1}{2}$ years, the others between 6 and 7 years of age. In two, intubation was performed first; in one, intubation, followed by an immediate tracheotomy; in the other, two days of respite were given; in the remaining three tracheotomy was immediately required. Three of these operations were done in three weeks. All but one were treated with antitoxin before the operation, one afterward; first dose administered immediately after the operation. All recovered without any paralysis or bad symptoms. The tube was worn from five to ten days, being removed as soon as air could freely pass through the larynx, and the wound allowed to heal by granulation. Very close attention was paid to the steps of the operation. In two cases chloroform could be administered safely; in the others it would have been dangerous. Strychnia was administered hypodermically in all but one case to stimulate respiration. Strict attention was paid to the after-care of the tube; the frequent removal and cleansing was ordered in every case where any sign of obstruction was noticed. This, together with keeping the tube moist if necessary, by the dropping of sterilized water into it, is the sheet-anchor of success in the operation. No medical treatment, except the use of strychnia, was given in these cases. The children were permitted to partake of wholesome and sufficient liquid nourishment with, occasionally, some stimulant. In all but one case the parents or near relatives did the nursing and performed it well. Such cases must never be left out of sight until all alarming

symptoms have disappeared. The whole tube was removed once every day by myself, the trachea examined, loosened membranes removed and the wound cleaned before the re-introduction of the tube. In all, cultures were taken from the detached membrane and the presence of Klebs-Loeffler bacillus demonstrated.

AN IMPROVISED APPARATUS FOR FIXING BLOOD-FILMS AT EXACT TEMPERATURES.

BY L. BREMER, M.D.

ST. LOUIS, MO.

The greatest of the many difficulties attending and complicating the study of hematology is the recognition and interpretation of the artefacts. Being a fluid, the blood with its corpuscular elements is more vulnerable than the rest of the tissues. This vulnerability manifests itself in response to mechanical and chemic injuries produced on the plasma, but especially the corpuscular elements in the course of the several modes of hardening or fixing the blood-film preparatory to the staining process.

Different methods, however slight the difference may be, will yield different pictures owing to the delicacy of the selective affinities of the constituent elements of the blood-corpuscles. By using chemicals such as alcohol, ether, or formol, as hardening agents, an element of uncertainty is introduced rendering results unreliable and ambiguous because of the possibility of existing impurities or variations in the percentage of water. The ideal hardening method is by heat. The disadvantage of this procedure has been the variableness of the heat degrees when Ehrlich's copper plate is used and the loss of time, to which may be added expensiveness, when a copper or iron oven is employed. The observance of the rule laid down in the text-books, to heat the blood-specimens up to 110 or 139 degrees C. leads to varying and conflicting results, histologically as well as micro-chemically. Every practical worker in hematology will testify to the puzzling difference of color and structure-pictures obtained in specimens of the same provenience, and sometimes in different areas of the same individual cover-slip preparation. This difference is often seen, all conditions being apparently equal. It was during my investigations of the blood-test in diabetes by means of certain anilin dyes that I discovered the extreme susceptibility of the blood elements to slight variations of heat as affecting differential and selective staining. Sometimes a difference of a few degrees, when in the neighborhood of the upper and lower heat limits would mar the reliability of the test. In order to eliminate the uncertainties resulting from arbitrary and unsystematic heating I strove to find the optimum temperature for hardening the blood-film and fixing the hemoglobin, and the time requisite to obtain uniformly good results. I ascertained that 135 degrees C. is the optimum temperature for cover slip preparations and that the time requisite to reach this temperature in the heating apparatus is about five or six minutes. These figures apply specially to the little improvised oven represented in the cut.

HOW TO MAKE THE OVEN.

Take a five ounce quinin can; bore two small holes through two opposite walls at equal distances, four

inches above the bottom of the can. Draw through them two copper wires, to support a square piece of wire screen cut to fit the interior dimensions of the can. A circular opening is made in the lid large enough for a perforated cord holding a thermometer, registering about 250 degrees C. In the four corners of the bottom of the can, holes having approximately the diameter of half a line are bored. They serve the purpose of establishing a draft for the proper circulation and diffusion of the heat. Unless the cork fits

very tightly in the opening made in the lid no holes are necessary in the corners of the latter. The cover glass preparations, smeared side up, are arranged in rows on the tray, care being taken that they do not overlies each other. The point of the bulb of the thermometer is to be adjusted in the same plane with the specimens on the tray. An alcohol lamp or a small gas jet may be used as heat generators. The temperature is run up to about 135 degrees C. in from four to six minutes. It is advisable to place the oven

on a tripod or other metal stand, in order to prevent shifting and overlapping of the coverslips. One or two degrees above 135 will not interfere with obtaining a good result. Have the cover glass slips or slides in a perfectly horizontal position.

With an apparatus like this, examinations of the blood may be made at the bedside. Another advantage of the contrivance is the facility and readiness with which the preparations may be heated; they will then retain their specific selective staining properties for months, whereas the film not properly hardened loses them in a short time. Its chemic properties are easily affected by the dampness of the atmosphere.

Exact temperatures are more easily obtained with the little apparatus described than larger and costlier ones.

SOCIETY PROCEEDINGS.

Denver and Arapahoe Medical Society.

Meeting of March 22, 1898.

THE SERUM TREATMENT OF TUBERCULOSIS.

Dr. F. E. WAXHAM reported a series of ten cases treated with antiphthieic serum T. R. (Fisch), and he prefaced the recital by the following remarks: "It is with very great reluctance and hesitation that I present this paper tonight. We all naturally dislike to advertise our failures, but in order to get at the true value of any remedy or mode of treatment it is not only necessary to tell the truth, but the whole truth. It is the honest desire to determine the value of the serum treatment and to elicit a discussion that may help us to arrive at correct conclusions that prompts me to present this paper. The unfavorable results will not, I hope, be ascribed to poor judgment or unskilful treatment. It does not require special skill to properly give hypodermic injections, and in proof that the remedy was properly given I would state that out of something like one thousand injections there has not been a single abscess or other evidence of careless administration. The remedies have been carefully given and the patients carefully observed, and in no case was there febrile reaction. In nearly every case, however, there appeared about the fourth or fifth day serum eruptions upon the back causing considerable itching and discomfort, lasting two or three days, then disappearing." The cases were reported *in extenso* in the JOURNAL for March 19, 1898. The summary of the treatment is as follows: Number of cases treated, 10; cured, 0; died, 1; improved, 2; worse, 7; bacilli present in 9 cases, bacilli disappeared in 1 case. "Judging from these cases, we may safely say that the serum treatment in well-developed or chronic tuberculosis is a failure."

Dr. BONNEY said that Dr. Waxham's conclusions are in perfect accord with his views on the subject. He has observed a good many cases under the treatment of his confrères. The subject should be considered from both the theoretic and clinical standpoints. The drift of opinion of the greatest clinicians in Europe is against the tuberculin treatment. In Professor von Leyden's clinic there has been absolutely no success with the treatment. He also quoted the statement that Dr. Huber, Leyden's assistant, attempted to immunize animals in the way in which Koch does, but he failed in every attempt. The experiments were carefully carried out, the dosage of tuberculin was exact and sufficient and the observations numerous enough to do away with the idea that perhaps coincidence played a rôle in the results obtained. Yet he failed to get the desired immunity. "After the supposed immunization all the animals died when inoculated with tuberculous material, and interestingly brought before the control animals inoculated with the same material at the same time." Not only does he consider the tuberculin treatment useless, but in many cases it is absolutely harmful. What the patients need is exercise, nourishment and fresh air. Patients receiving the tuberculin treatment have to see the physician daily, they have to come down town and wait sometimes for half a day in the close atmosphere of the waiting room. The patient is thus deprived of the fresh air, the sunshine and exercise. He has seen a good many cases who have improved after the treatment was discontinued.

Dr. A. M. HOLMES said that he had had ample opportunity for investigation. He was one of the very first who took up the tuberculin treatment and he was greatly disappointed at the conclusions of Dr. Waxham. They do not accord

with his experience. He has reported in the JOURNAL a series of cases treated with the serum and they were of such a nature that all stages of the disease were represented. All of Dr. Waxham's cases fall within the category of one of his cases, namely, No. 8, which is by no means a favorable case for tuberculin. The pathology of tuberculosis must not be lost sight of. Like diphtheria, tuberculosis is a toxic disease, but in addition the tubercle bacilli are a new growth, which is entirely devoid of blood vessels. The tubercles undergo fatty degeneration and offer a nidus for further development of the disease. Being devoid of blood vessels the serum can not reach the seat of disease after it has advanced. It is only in early stages of the disease that we can expect to do some good. Because diphtheria under the antitoxin treatment shows a certain mortality there is no reason why we should abandon the treatment.

Dr. DENIM said: I read the report of the cases presented by Dr. Waxham in the JOURNAL received yesterday and at once concluded there was in these results a confirmation of an impression I had gained that we were more and more getting the transmitted effect of tuberculin as the dosage of the animal furnishing the serum was increased. In none of my cases reported to this society up to December 3 had I given the serum treatments every day, as in all these ten cases reported, but every second or third day. Even then, with less than half the total quantity used by Dr. Waxham in a given time, I began to notice increased reaction and effects. This was soon after reading my paper (December 14), and coincident with their reaching the largest immunizing dose given their horses in St. Louis (supposedly 100 c.c. of Koch's new tuberculin), I wrote to the manufacturers about this and tried to learn the dosage and time afterward that the serum of different dates was drawn. I received a reply from Dr. Fisch informing me that all the serum was made of the same strength but withholding the details I desired. For this reason, with the less favorable results I was then having, I gradually discontinued the use of the remedy.

Now Dr. Waxham's continuous two months' daily use of this serum was mostly since that time and therefore I say there is reason to suspect that either the dosage of the horses was getting to be too large, or the commercial demands for the serum may have led to the shortening of the period when the horses were to be bled.

This brings up the question I raised in my paper as to the possibility of there being a *transmitted* tuberculin or a *mixed* effect in antitubercular serums, and also whether this *indirect* way can be equal in immunizing power to the *direct* creation of antitoxin principle in a patient's blood. Thus far preference for the latter method is warranted by all the experience of which I can learn. My own results on this latter plan have been more satisfactory and lasting than by the indirect (serum) method. On account of the uncertainty involved it is a questionable procedure to crowd the use of this strong serum by *daily* use of the full doses advised. If there be, as with strong serum treatment there probably is, an uneliminated though indefinite reactionary influence left over from one injection to another, then there must eventually come a cumulative result which will be the reverse of what we are after. The affected system becomes surfeited with an effort, at first decidedly remedial, which is likely to be exhausting some time later.

The majority of these cases here reported for discussion are evidently too serious for such an heroic method. If, as the evidence seems to show, they were having a "good thing" during the first two weeks, they were getting decidedly too much of it during the seventh and eighth weeks. The ten cases reported would, in my judgment, have done far better even on crude tuberculin (given in very small doses with two or three days interval according to Dr. Whittaker's plan), not to mention the preference for the later improved derivatives of tuberculin, and I imagine the resulting immunity would be more genuine and lasting than that obtained by any serum yet discovered. Nobody knows exactly what we have in an antitubercular antiphthisic serum. The conversion of the tubercular toxin into an antitoxin in an animal's blood is not yet a clearly determined proposition either as to its completeness, the time required, or the quantity possible to be so converted. It may be that we are near to obtaining a pure antitoxin for tuberculosis created outside the affected human body. It may be that at the start Dr. Fisch was very near it, or that Dr. Hirschfelder may show that he has found the equivalent of an antitoxin; but as yet it seems that in any antitubercular serum we have only "mixed goods" and what we want is the pure article. So far as I can determine the conditions are not definitely known which will produce a pure antitoxic for tuberculosis, for instance as direct and pure as the diphtheria antitoxin.

For the present we had best content ourselves with the direct

method which involves, or ought to be accompanied by, the strengthening of the individual resistance of the patient by every other possible means, such as climate, good feeding, exercise and a proper individualizing management suited to the case in hand.

Dr. WM. N. BEGGS—I happen to have come from St. Louis where, as you know, two serums for the treatment of tuberculosis are produced. The first was prepared by Dr. Paul Paquin. Mr. T. F. Milliken was his business manager. The second is the product of Dr. Carl Fisch, Koch's T. R. tuberculin being the immunizing agent. Mr. T. F. Milliken is now his business manager. I have met both of the medical gentlemen.

It was my fortune to hear Dr. Paquin read the first report on the use of his serum before the St. Louis Medical Society. At that time I knew nothing of the cases, patients in the St. Louis City Hospital, and consequently could form no judgment as to the worth of the report. Since then I have learned, from some of the then assistant physicians of the city hospital, facts which led me to believe that the sources of error had not been eliminated. This I believe to be the case in nearly all of the cases of tuberculosis treated with serum throughout the country. I doubt the value of either serum in the treatment of tuberculosis. As we all know, the consumptives coming into charity hospitals are in the habit of knocking around the country, subject to all kinds of hardships and privations, until they have to give up and go into a hospital. Then, under the influence of quiet, rest, and nourishing food, they rapidly improve for a time regardless of the line of treatment pursued. Not until the full result of this hospital benefit has been reached is any opinion as to the effect of the medicinal treatment justifiable. The cases referred to as forming the subject of Dr. Paquin's first report were mostly patients in the St. Louis City Hospital, a charity hospital. They were taken as they entered the hospital, not after the full effects of the hygienic influence of the hospital surroundings had been reached, and placed under the serum treatment. Consequently that source of error (no small or unimportant one) had not been eliminated, and the general improvement can not be properly accredited to the serum.

Dr. Fisch's serum I have used in only two cases. Neither was a favorable case for any line of treatment and the results were correspondingly bad.

As Dr. Bonney had said, this subject must be considered from the scientific as well as clinical point of view. The question arises: Because the serum treatment has had most gratifying results in certain infectious disorders, must we necessarily conclude that that is to be the successful line of treatment in tuberculosis? There are certain differences between tuberculosis and those diseases in which the antitoxin treatment has shown conclusively successful results which it is well for us to bear in mind.

1. Those diseases are essentially acute diseases; tuberculosis is not.

2. Those diseases are strictly toxicemic diseases; tuberculosis is a neoplastic disease as well as toxicemic.

3. In those diseases the retrogressive changes are such as may be recovered from without loss of tissue; in tuberculosis there is always absolute destruction of tissue.

4. In those diseases the bacteria are not scattered throughout the tissues, but have a definite localization. The source of toxin formation is single, not multiple. In tuberculosis the opposite is the case.

5. In those diseases the source of the toxins is usually readily accessible to the therapeutic agents. In tuberculosis the bacilli are within a neoplastic tissue, a non-vascular tissue. This means that in them the movement of the tissue fluids is exceedingly sluggish, in the necrotic centers practically absent. Consequently the therapeutic agents fail to reach the source of trouble.

6. In those diseases the bacteria are usually destroyed or discharged from the organism quickly; therefore the administration of the antidote to the toxin is continued for only a very short time. In tuberculosis the tubercle bacilli are continuously present for great periods of time, and the administration of the antitoxin would necessarily be as protracted.

7. In most of those diseases (diphtheria is an exception) the survival of an attack confers an immunity to the individual. No such thing is known in tuberculosis.

8. Those diseases are all self-limited diseases. If the immediate intoxication is not too great and the patient survives for a really short time, he recovers. There is no characteristic self-limit to tuberculosis. The statements justify us in asserting that it is utterly impossible for an antitoxin to be the proper and specific therapeutic agent; but, in view of them, we are not justified in drawing the conclusion from analogy that it is the rational treatment.

Two other points raised in the discussion I wish to make.

The first is in reference to the degenerative change occurring in the tubercle. The characteristic and constant retrogressive change in the tubercle is not fatty metamorphosis, as has been stated, but coagulative necrosis. The other is in reference to the prognostic value of the number of tubercle bacilli to the field occurring in a cover glass preparation of sputum. I believe there is no more fallacious standard upon which to base our prognoses. I have repeatedly had the experience that in one film I would meet with untold myriads of tubercle bacilli, whereas in many other films from the same sputum they would be present in moderate numbers only. Again, it is not infrequently the case that in making daily examinations of the sputum in the same individual the bacilli would be comparatively few for a number of days, then for a day or two very numerous, to be followed by a period of comparative sparseness. I repeat that I believe this the most fallacious means of arriving at a prognosis.

Dr. SIMON has had three cases and none have shown signs of improvement. One case showed alarming symptoms at first which, however, soon subsided. He has given the treatment a fair trial. The cases were favorable for treatment.

Dr. EDSON—Early cases will do well under climatic treatment. What we look for is some reliable treatment in the advanced cases, and this everybody seems to admit that the tuberculin T. R. does not offer.

Dr. WHITNEY summarily deprecated the use of the serum. He followed closely the literature on the subject, and he concluded long ago that it would not be worth while to subject his patients to this experimental treatment.

Dr. MUSSEY—This discussion has been to me an apt reminder of the proverb that "a prophet is not without honor save in his own country." The trouble with this remedy seems, in part to be that it is produced too near home. The tone of the discussion, tonight, in reference to the remedy has been, in the main, condemnatory. This, I consider as uncalled for. I was sorry that the essayist did not elaborate more fully the cases reported, especially in reference to the action of this serum.

My own experience in the use of Fisch's serum has been limited to the treatment of seven cases. These cases, two in incipient, three in moderately advanced, and two in advanced stages, have been carried through an average of two and a half months' course of treatment. I will say that my experience has been disappointing only in that I have failed to obtain remarkably good results, not that any case has been injured through the treatment. Three of these cases gained materially in weight, one patient making a gain of twelve pounds in three months. That this remedy is in any regard a specific, is not in my opinion to be credited. It has failed to modify temperature, to check night sweat or to modify the character or quantity of the expectoration in the time we were lead to expect such results. Beneficial results have occurred only in those cases in whom we would look for improvement through our climatic advantages. Several of these cases have shown peculiar reactions from this serum. Rashes, localized and distributed urticarias, temporary enlargements of the axillary glands and on two occasions alarming symptoms have been manifested due to the too sudden ingress into the circulation, as embarrassment of the respiration amounting to extreme dyspnea, cyanosis, swelling of lips, eyelids and transitory circulation embarrassment. With the exception of these transitory reactions, no unfortunate results have occurred in any case, and nothing has transpired to lead me to believe that I was dealing with a dangerous remedy.

In going over to a theoretic discussion of a tubercle antitoxin it is hard to believe as has been suggested this evening, that a toxin can be carried through the body of a horse for months to reappear again in the serum of that horse's blood as a toxin, when the animal has for weeks recovered its normal condition of health. It is still more difficult of belief that a complete immunization of animals has been secured. It is my belief that the future specific will appear through the serum of artificially immunized animals, and I would deprecate the making light of work which is being conscientiously carried forward in this direction. As has been most ably presented this evening, the difference in the pathologic process of tuberculosis from other affections in which antitoxic cures have been perfected, the fact that here there is no self-limited affection, and that a neoplastic formation takes place in the tissues, argues only the difficulty of the problem, and presents only the barriers which must be surmounted, but in no way proves that these difficulties may not be overcome, and science be made to score a new triumph.

Dr. M. H. MACK read a paper on the "Necessity of Early Operation in Cases of Abscess About the Rectum." Delayed operations, he said, are etiologic factors in fistula ani. The

subject was discussed by Drs. S. D. Von Meter, Stover and Spivak.

Chicago Ophthalmological and Otological Society.

Regular meeting held March 8, 1898.

President, W. F. COLEMAN, in the Chair.

LARGE EPITHELIAL FLAP GRAFTED ON THE EYEBALL IN A CASE OF EPITHELIOMA OF THE CONJUNCTIVA.

Dr. F. C. HOTZ—I wish to present tonight a patient from whose right eye I removed a large growth February 7. The growth started in the conjunctiva near the sclerocorneal border. I have here two pictures showing how it appeared in August and in December. You will notice that the growth is very vascular, and there is a good deal of engorgement of the conjunctival and subconjunctival vessels. The tumor invaded the corneal margin to a slight degree, about a millimeter or a millimeter and a half. Below the growth the corneal margin showed a narrow stripe of thickened epithelium and the adjoining conjunctiva was also thickened just as we observe it in beginning pterygium. In removing this growth I dissected it off from the cornea carefully, and I also took out with it the suspicious-looking part of the conjunctiva below. This left quite a large defect on the eyeball; the sclera was exposed and the conjunctiva was much retracted so that there was no possibility of covering the wound by sliding the conjunctiva over it. I therefore resorted to grafting, and I should have done the Thiersch grafting, as I have done in a number of operations for large pterygia, had it not been for a suggestion Dr. Gifford made in a paper published in the December number of the *Ophthalmic Record*. I have always felt disinclined to use mucous membrane, because in cutting the flaps out with forceps and scissors you get more tissue than you want, and especially submucous tissue. You have then to prepare a flap, turn it over and clean it, a procedure which in such a delicate structure as the mucous membrane is not easily carried out. That is one of the reasons why I prefer Thiersch grafts, because they are so easy to handle. Dr. Gifford recommended cutting what is called an epithelial lip-flap with the razor, so as to get a thin strip of say one half thickness of the mucous membrane. I resorted to that method. After the operation on the eye was done I took the lid clamp and clamped the lower lip into it with the ring on the mucous side and used a drop of holocain, with which I anesthetized the area of mucous membrane within the clamp; as quickly as I can say it, anesthesia was obtained, and then with the razor I could shave off a flap without causing any pain. I took an epithelial flap about one centimeter and a half long and one-half a centimeter wide. This flap floating on the razor, in sterile salt solution, was carried to the eye and dumped down so that it floated from the razor with the proper side down on the eyeball and spread out. The graft was so large that I mistrusted somewhat its security by leaving it without tying it fast. After it was spread out I allowed the patient to close the eye and then open it again, and I saw it had shifted and wrinkled a little. To make sure I took fine silk sutures and fastened the graft to the upper and lower borders of the conjunctival wound, so as to have it fastened at these two ends to prevent its slipping. As you see, the eye has made a nice recovery, and the epithelial graft makes a perfect substitute for the lost ocular conjunctiva.

The case is very interesting from another point of view, and that is with reference to the nature of the growth. It was very vascular, and in dissecting it off bleeding was quite profuse. The microscopic examination, which was made by Professor Herzog of the Polyclinic, showed that it was an epithelioma of the conjunctiva. Dr. Herzog was kind enough to furnish me with this very nice drawing and several slides, but I am sorry I did not bring the slides with me tonight. The drawing shows the growth of epithelial masses down into the connective tissue. From the microscopic examination of the specimen we could come to no other conclusion than that it was an epithelioma of the conjunctiva. The epithelial cells are flat and cylindric toward the deeper part, showing plainly that the masses are growing into the subepithelial connective tissue. The growth is quite rare. Cases of carcinoma of the conjunctiva are not frequently reported. In looking over Graefe's *Archiv*, for instance, I could find reports of only half a dozen cases. One of the cases was reported by Graefe himself, who gave a description which is very much like the clinical picture presented in this case. It was a case which at first was thought to be a large and unusually obstinate phlyctenula, with marked injection of the surrounding ocular conjunctiva. He removed the tumor and Virchow made a microscopic diagnosis of epitheli-

oma. In that case, after a year there was no recurrence. In my own case I think the prognosis, on the whole, is favorable, inasmuch as the microscope shows that it is rather a slow growing tumor, and as I succeeded in covering the wound, which healed kindly, there is good chance for the eye to escape a recurrent attack.

Dr. FISHER exhibited an interesting case of

PARALYSIS OF BOTH ABDUCENS,

with contraction, not only of the muscles that rotate the eye inward, but of the orbital tissues.

Dr. J. E. COLBURN—Last winter a patient came to me with one eye very much in the same position that we find this patient's two eyes, and with a history that when 6 years of age the eye became convergent and had remained in its converged position ever since. When I saw him the conjunctiva was red from exposure. He was an out-of-door man. I advised enucleation, as the other eye was perfectly good and the affected one was very unsightly. Before advising enucleation, however, and after using cocaine, I found I could not move the eye by forcible means any more than could Dr. Fisher in his case. I obtained the consent of the patient, and enucleated the eye. I found it about one-third longer than the normal eye in its antero-posterior diameter, and very irregular in form. I could not find the adductor muscle, and the abductor muscle was almost equally obliterated, but the connective tissue at the inner canthus was firm and cicatricial. The man assured me that so far as he knew he had never had any inflammatory condition of the eye.

PRIMARY CARCINOMA OF THE CONJUNCTIVA.

Dr. C. D. WESCOTT—I would like to describe a case recently seen in which as yet no microscopic examination has been made. The patient is 67 years of age, and presented himself with a tumor which overhung the cornea, evidently growing from the eye just up and out from the cornea, and which was beginning to slough. It was not feasible to remove the tumor from the eye, though the cornea appeared normal, and it was impossible to tell before the eye was removed whether the tumor was partly intraocular or not. Enucleation was performed, and upon making section of the eye no abnormality was found within the globe. The tumor had its origin from the conjunctiva just without the limbus, up and out. It is not pigmented and has the gross appearance of carcinoma, and I believe it to be primary carcinoma of the conjunctiva. The growth had extended back underneath the conjunctiva somewhat, and in making my enucleation I removed a portion of the fornix in order to get all the tumor. The specimen is now being hardened for microscopic examination, and I shall show a slide of it at some future time.

The beginning of the tumor was like that of the one described by Dr. Hotz. It appeared as a little reddened pimple and grew slowly, having reached the size it finally attained after three years. The man was a farmer, and remote from any physician, and nothing had been done for the eye until he came to see me, at which time the tumor had begun to slough at the apex. The tumor was so large that the lids were widely separated and it was constantly exposed and irritated.

EPITHELIOMA OF THE CONJUNCTIVA.

Dr. J. E. COLBURN—Some of the members may recall the case of a physician that I reported two years ago, from whom I removed a malignant growth from the cornea, or rather destroyed it. It involved the conjunctiva toward the inner canthus. I removed the growth the first time thinking it was a pterygium. The second time I removed it, knowing it to be a malignant growth, and the third time I destroyed it as thoroughly as possible with the galvanocautery. The tissues were so much involved that there was absolutely nothing that could be removed without destroying the sclerotic. I burnt over nearly one-third of the corneal surface and quite an area of conjunctiva. It has now been nearly three years this spring since I removed the tumor and there are no indications of its recurrence. There was a good deal of astigmatism following the burning, but the eye assumed its normal condition and the translucency of the cornea is good, and vision is better than it is in the other eye.

PRIMARY EPITHELIOMA OF THE GLOBE.

Dr. W. F. COLEMAN—I will relate a case that came under my observation some eight years ago. I can not describe it as minutely as I would like to do. The case was that of a man 40 years of age who presented himself with a growth on the left sclera between the cornea and external canthus. The growth was circumscribed and slightly pedunculated. I suggested snipping it off, but the man objected and did not report for about six months, when it had increased to the size of a small bean. It had grown so rapidly and was so vascular that

I diagnosed an epithelioma and suggested its removal at once, telling him that he would lose his eye if he did not submit to an operation. I removed the growth and gave the specimen to Dr. Casey A. Wood, who examined it and pronounced it epithelioma. It is the only case of primary epithelioma of the globe I have seen.

Dr. C. P. PINCKARD—Dr. Tilley showed a case to the Society about a year and a half ago in which the cornea of both eyes were turned in and down, and in this case there was slight motility of both sides as in Dr. Fisher's case. Dr. Tilley's was, however, a congenital case.

Dr. W. W. WHELOCK, Fort Wayne, Ind., reported cases and exhibited specimens.

RHINOLITH OR FOREIGN BODY.

Dr. Wm. L. BALLENGER—I have a specimen which I did not intend to present tonight, but it has been suggested that I do so. This specimen was removed from the nose of a patient at the Eye and Ear Infirmary some two or three months ago. The case was in the service of Dr. Wilder. The man was 60 years of age, upon whom Dr. Wilder had operated for cataract, and noticing an offensive odor from the nose he suggested that he have his nose examined and treated while in the institution. One of the internes, Dr. Ainsley, examined the man's nose and made a diagnosis of rhinolith, and with his assistance I removed it from the nose. The offensive odor had been present for about thirty years. At the time I removed the foreign body I supposed it to be an ordinary rhinolith, as it had all the appearances of it. Some two months later I removed the exterior portions of the specimen and before I had gone very deeply into it I found a piece of iron. Upon cleaning it up a little more it was seen to be the breech-pin and nipple of an old-fashioned percussion-cap musket. The man stated that thirty years ago a gun had exploded, destroying his left eye. He is now in the State of Illinois somewhere and I intend to look up the record of the case more fully and ask him for all particulars concerning the explosion. This portion of the gun [exhibiting] passed in through the orbit and possibly lodged in the ethmoidal cells or in the antrum of Highmore. After a time the walls sloughed away and the specimen lay loose in the nose. It could be moved back and forth an inch and a half. With the aid of a strong pair of dressing forceps I succeeded in removing the specimen. The man objected to taking an anesthetic. The specimen is much smaller now than when I first removed it. It weighed at that time 325 grains.

CATARACT.

Dr. C. D. WESCOTT—I would like to recount another interesting experience which I have had recently. A woman came to have an operation for cataract. She was 73 years of age and gave a history of blindness in one eye for twenty-five years. There had been no involvement of the other eye until very recently. On examining the good eye I found beginning peripheral changes in the lens, with some senile changes in the fundus, and gave a very unfavorable prognosis in regard to the other eye. The patient was prepared for operation, however, and I proceeded to extract the lens. I expected to encounter a Morgagnian cataract, but when the thickened and opaque capsule was ruptured the contents proved to be entirely fluid and about the consistency of ordinary pus. There was a good deal of cholesterolin present and some gelatinous matter, but there was absolutely no trace of solid nucleus. I coaxed it all away by gentle manipulation of the cornea without any difficulty and extracted the capsule entire with the iris forceps. Healing was ideal, with scarcely any hyperemia of the eye at any time. The bandage was discarded on the seventh day after operation, and vision with correction two weeks after operation is 20_{100} , although the eye had been divergent for many years, and for twenty-five years she had seen nothing with it. It was interesting to see the eye straighten up and vision gradually come to it as the tests were made. Examination with oblique illumination shows a single thread of capsule across the pupil and a number of cholesterolin crystals can be seen clinging to it. The iris is tremulous, just as we see it in cases of dislocation of the lens.

Dr. W. F. COLEMAN—I would like to ask if any of the members have had any experience in washing out the chambers after extraction. Personally I have had no experience with it. Possibly it may be an advantage in preventing the necessity for a secondary operation.

Dr. F. C. HOTZ—In regard to Morgagnian cataracts without solid nucleus, these cases are rare. Usually we find small solid lenticular nuclei, and if the capsule is clear the optical results are very good. It is surprising that Dr. Wescott did not get more vision than $21_{100}+$ in his case, and it would be interesting to watch it and see whether education will bring back the sight; whether it is a case of amblyopia from non

use, as this is still an unsettled question. It would be interesting to see whether the vision of the operated eye will gradually improve when the cataract in the other eye progresses so as to make its sight dim and useless.

Dr. C. D. WESCOTT—Undoubtedly vision will never be good, because of the amount of choroiditis in the eye. Both eyes are equally involved in senile changes of the choroid. However, as it is not uncommon to see vision of 20_{70} or 20_{100} two weeks after operation increase to 20_{30} and better, it may do so in this case.

Dr. COLEMAN—How long has the eye been divergent?

Dr. WESCOTT—I can not say positively, but she said a great many years. Sight failed slowly at first, beginning twenty-five years ago, and for a great many years the eye had been divergent.

Dr. W. F. COLEMAN—In talking with Dr. Lippincott two years ago he said he had tried physiologic salt solution, and had finally resorted to 0.5 per cent. solution of boric acid. He claims that it is very rare that a secondary operation is required. If this is accomplished I am sure the risks of cataract are very much reduced. So far as reports go the risk attending secondary operations is six times as great as that in primary operations.

Dr. F. C. HOTZ—You say, Mr. President, that you had a conversation with Dr. Lippincott two years ago?

Dr. COLEMAN—Yes, sir.

Dr. HOTZ—Last summer Dr. Lippincott told me that he had given up washing out the anterior chamber after operations. I have always regarded the washing out of the chamber as unnecessary, because removed particles of lens matter in the anterior chamber are harmless and get absorbed, and I have never washed out the capsule, because it looks to me a hazardous procedure to resort to these injections after the eyeball is opened, when there is nothing but the tender, slender posterior capsule to hold the vitreous back. To poke around with the nozzle of a syringe in the capsular sac for the sake of removing some lens matter adhering to the capsule is dangerous, and I do not think any gentle washing would remove the particles. Besides, these particles are eventually absorbed and do not play an essential rôle in the production of secondary cataracts. These are chiefly caused by wrinkling of the capsule and inflammatory processes.

Dr. W. F. COLEMAN—Has any one had any experience in removing the anterior capsule with forceps instead of using the cystitome?

Dr. GRADLE—I have tried it a number of times but did not always succeed. If the capsule is very much thickened then you can succeed, but in my cases there was not very marked thickening of it.

MORGAGNIAN CATARACT.

Dr. C. D. WESCOTT—I saw an interesting case of Morgagnian cataract in Philadelphia last June in the clinic of Dr. de Schweinitz. The patient was a woman about 75 years of age. After the iridectomy the capsule refused to be cut. Dr. de Schweinitz made two or three forcible efforts at incision, and then with a good deal of pressure delivered the nucleus, which was floating in fluid in the capsule. It was like a little pebble in a string sack containing fluid. He lost about six or eight minims of vitreous because his efforts at the delivery of the lens were necessarily quite forcible. He closed the eye after a hasty cleansing, and subsequently wrote me that the wound healed kindly. I have forgotten what the vision was, but it was good for such an eye.

Dr. C. P. PINCKARD—Did he take it out with a scoop?

Dr. WESCOTT—He simply depressed the upper lip of the wound with a spoon, making pressure upon the lower border of the cornea with a spatula and squeezing it right out. As it popped out some of the vitreous escaped.

Chicago Gynecological Society.

Regular Meeting held March 25, 1898.

The President, Dr. HENRY P. NEWMAN, in the Chair.

Dr. C. S. BACON showed a specimen of

HYDROCEPHALUS.

Sickle, he said, had collected statistics of 65,000 births, and found the frequency of hydrocephalus to be 1 in 6000. Lachapelle, in 50,000 labors, found the frequency of hydrocephalus to be 1 in 3000, while Winckel found its frequency to be 1 in 2000. The number of deaths following delivery was about 25 per cent., and of these about 13 per cent. of the cases were due to rupture of the uterus. The head measured after delivery, and after the fluid contents had been evacuated, in the occipito-mental circumference, fifty-one centimeters. The patient was

a primipara in the thirty-eighth week of gestation. Forty-eight hours after the membranes had ruptured he saw the patient and found the uterus very much distended in its lower segment and in a state of tetanic contraction. The patient was anesthetized, the head punctured, a cranioclast applied and the head extracted. Following the extraction of the head, the contents of the uterus behind the child, which had become putrid, were expelled. The placenta was expelled by Credé. The patient was rapidly convalescing.

Dr. REUBEN PETERSON showed

FORMOL GUT IN HERMETICALLY SEALED GLASS TUBES.

When he began his abdominal work he feared the use of catgut on account of his inability to render it absolutely sterile, and he had used silk almost altogether. Increased experience, however, had convinced him that catgut should be used, if it could possibly be rendered sterile in any way.

Dr. ALEX. H. FERGUSON said that sometimes bad results from catgut were attributed to the catgut, but the catgut itself was not at fault. The fault might be with the nurse, the receptacle containing it, the assistant, or sometimes with the surgeon himself. The catgut prepared by Mr. Hollister, and put in sealed tubes, as advised by Dr. Peterson, recommended itself to him as being surgically ideal. The speaker had performed a number of experiments with a view to determining the length of time in which catgut would become absorbed, and finds that aseptic catgut becomes absorbed more rapidly than antiseptic catgut which is hardened with pyoktanin. That which remains the longest of all in the tissues is chromicized catgut. Very stout chromicized catgut remains in the tissues six weeks.

Dr. ALEXANDER H. FERGUSON read a paper on

URETERO-VAGINAL AND URETERO-ABDOMINAL FISTULÆ,

in which he reported two cases of ureteral fistula that occurred in his practice, and which led him to investigate this interesting and comparatively rare surgical affection. The essayist had collected sixty-five cases, which with the two of his own, made sixty-seven cases in all. Of this number sixty were uretero-vaginal, four uretero-uterine and three uretero-abdominal. This does not include fistulæ from the kidneys, nor the uretero-lumbar and uretero-inguinal varieties. No cognizance was taken of the various primary operations performed on patients, accidentally injured ureters while operating upon the pelvic organs. The ages of the patients varied from 19 to 64 years, excluding those persons having the congenital forms. The author then dwelt upon the etiology, and considered at some length operations and results, after which he reported his two cases in detail.

He drew the following conclusions from the sixty-seven cases of ureteral fistulæ reported:

1. The left ureter is more frequently the seat of trouble than the right.
2. The most frequent variety is the uretero-vaginal, and the rarest is the uretero-abdominal fistula.
3. The most common cause is difficult labor; and forceps delivery is a prominent etiologic factor.
4. Of all the operations performed in the pelvis, vaginal hysterectomy is the most frequent cause of ureteral fistula.
5. Other conditions being favorable, all cases of ureteral fistula are curable by operation: *a*, In all cases of uretero-vaginal fistula the direct method of operating should be selected and no particular operator's method is applicable to all cases. When the ureteral opening is situated close to the bladder, Schede's operation is the most surgical and is applicable to the greater number of cases; when situated far away from the bladder, as in my case, a plastic operation on the principles carried out by me should be tried before a graver or more mutilating procedure is thought of. Intra-peritoneal operations are suitable for the abdominal fistulæ.
6. For the cure of uretero-vaginal fistula, it is in my opinion absolutely unjustifiable to perform hysterectomy, nephrectomy, or colpocleisis. When septic infection of the kidney occurs it may be necessary to open or remove it. It bespeaks lack of surgical ability to remove a kidney, a uterus, or close a vagina in these cases of simple fistula.
7. Another procedure which I think uncalled for is transplanting of the cervix uteri into the bladder for the treatment of uretero-uterine fistula, for it causes sterility and the menstrual flow is abnormally directed, and besides a disturbed bladder might cause a backward flow of urine into the uterus, Fallopian tubes or even peritoneal cavity, depending upon the condition of the organs.
8. Directing the urine into a bowel is only justified when any other operation can not be performed. While uretero-enterostomy has been successfully performed it has but little to recommend it on general principles.

Dr. FRANK A. STAHL read a paper entitled

SOME OBSERVATIONS ON THE TREATMENT OF ANTEMATURE LABORS, ESPECIALLY OF ABORTION,

in which he said that when the physician of experience is called to a case of mature labor, in the conduct of it he is guided by a policy, the fruit of a ripened clinical experience, which he indicates in the brief but expressive sense, "trust nature, interfere only when necessary." Therein he but reflects the scholastic doctrine, "interfere then when danger presents to mother or fetus." Nature teaches that in all forms of labor, whether at the first month or at the tenth, the stages and principles of labor are always the same, the details of technique only modifying to meet the indications of the case. Can these generalizations, applicable to labor at term, be applied with equal safety to antemature labors, the abortion, the immature and the premature labor? He thinks so, and further believes that if he will be so guided, the general practitioner or the experienced accoucheur will never be too late with his assistance, and less often guilty of dangerous though well meaning anticipatory assistance. The results, so far as the attendant is concerned, will always depend upon, 1, the significance attached to the indication; 2, the method chosen to treat the indication, both being interdependent.

In illustration of his line of argument three cases were cited by the author from the literature of the subject, one resulting fatally from too conservative measures, and the other two beautifully illustrating how the pendulum had swung to the other extreme of radicalism, where major operations were undertaken to overcome minor conditions. A method to be proper and successful, possessing sufficient elasticity to meet the requirements of all cases, must combine the elements of both the so-called conservative and radical procedures, but without the extremes of each, viz., be conservative in the presence of a normal course abortion; be radical in the presence of an abnormal course abortion.

The author divides abortions into:

Normal course abortions.—Those where (1), dilatation occurs without pathologic manifestations; (2), expulsion of fetus in abortion is of little or no importance; (3), expulsion occurs *en masse*, or where retention with dilatation of os continues no longer than twelve hours, that is, from morning till night, or night till morning, in both cases without pathologic manifestations. Here he favors the conservative method, to pack and wait, giving nature an opportunity to act.

Abnormal course abortion.—(1), Where dilatation progresses so slowly as to cause serious exhaustion, both physical and mental; this is an experienced sense; (2), where, with dilated os, retention continues longer than twelve hours. The dangers of exposure are too serious to chance anything, notwithstanding an exceptional favorable case; (3), all abortions where there is danger, regardless as to character, as from infection, serious hemorrhage, chill, sepsis, or any other condition indicative of danger. Here he favors the radical, empty-at-once method of treatment. These phases of abortion and their treatment were dwelt upon at length. In the treatment he divides abortions into two classes: *a*, those in which dilatation is incomplete or *nil*; *b*, those in which dilatation is complete. In abortion the first stage is only complete when it is such that the important passenger, the secundines, may pass.

To favor dilatation the author uses laminaria tents, notwithstanding objections raised to their use in many directions. He believes the unfavorable results of the laminaria tent have been due to the errors of the operator rather than to the use of the laminaria tent, *per se*: he rejects *in toto* the sponge tent. Often the secundines with dilatation may be simply removed with placental forceps, blunt curette or hooked out with finger.

In the manner of performing curettage, the author said there are those who prefer the blunt curette, and some the sharp curette. Personally, where there is a choice, he prefers the finger, and believes that in abortions, as in other forms of labor, to remove the secundines there is no instrument that for safety, information, thoroughness, and differential diagnosis, is equal to the finger. In the choice of the finger to curette, the speaker differs from Lusk, in that he uses the middle instead of the index finger, stating that it has a longer reach, swivels better, and is stronger. He claims, with the finger, to have always avoided the unpleasant necessity for secondary curettage with the dangers from primary secundine skipping, which is the especial and not seldom occurring danger with instrumental curettage. Thus vital energy is conserved and convalescence established with less exertion. Having emptied the uterus, he irrigates with warm (not hot) 2 per cent. carbolic solution, not especially for its germicidal effect, but for its cleansing, stimulating and alterative quali-

ties. He has never found it necessary to pack the uterus after curettage, notwithstanding he has encountered many septic and septic cases. The speaker then reported six instructive cases.

DISCUSSION.

Dr. C. S. BACON said the dangers of abortion were chiefly two, sepsis and hemorrhage. He agreed with the essayist that the indications for hysterectomy in cases of sepsis in abortion, and after labor at term, must be extremely strict, although there was a tendency at the present time to remove the uterus when the indications were not sufficient to warrant it. The measures for the management of incomplete abortion were considered under three heads. 1. The method recently recommended and advocated by Dührssen, of packing the interior of the uterus with iodoform gauze, thus producing strong uterine contractions, expulsion of the entire contents of the uterus and the remaining portions of the egg. 2. Removing the remaining portions of the egg with the curette. 3. Removal of the egg by means of the finger. The advantages of the finger were the greater certainty of diagnosis of the exact condition, and the more complete removal of secundines. He called attention to the dangers arising from the use of the finger. Its use required a larger dilatation of the cervix than the curette. If the cervix was dilated by a rapid dilator there was danger of tearing it, and of producing injury. Sometimes rupture might take place. He believed the essayist was correct in objecting to rapid dilatation in order to introduce the finger. He referred to the danger from dilatation by laminaria tents. The curette could be used without dilatation of the cervix, and the uterus could be cleaned out at once with it, which was an important consideration when there was any infection or elevation of temperature. The only two objections to the curette were the danger of perforating the uterus and of leaving some of the secundines. With the proper kind of curette there was no special danger of perforation. The leaving secundines behind or portions of membrane was due to lack of care.

Dr. REUBEN PETERSON thought the time had gone by for the use of laminaria tents in gynecology. He thought no more dangerous method could be adopted for dilating the cervix, whether puerperal or non-puerperal, than the introduction of a laminaria tent. He considers every abortion as an abnormal condition of the uterus, and such patients were fit subjects for surgical operations, and that whenever he has a case of inevitable abortion he treated it as a surgical case. He was also convinced that there was a field for hysterectomy in certain cases of abortion. He agreed with Dr. Bacon as to the use of the finger in cases of abortion.

Dr. SAMUEL L. WEBER thought Drs. Bacon and Peterson were a little too severe on the use of the finger in cases of abortion. He agreed with them that in the majority of cases the physician could not get along with the curette alone, particularly in inevitable abortions before the second month, when the egg itself was small. However, there were many cases in which it was absolutely essential to use the finger. A curettage for incomplete abortion could no more be thoroughly done, in his opinion, without the woman being under the influence of chloroform than a curettage for endometritis.

Dr. ALEX. H. FERGUSON said he made a distinction between those cases that had and those that had not been tampered with. The cases in which a sound had been passed, either by the patient or a physician, were usually septic from the start.

Dr. HENRY P. NEWMAN directed attention to a paper read by him before the AMERICAN MEDICAL ASSOCIATION last year on abortions, in which he presented his method of dealing with these cases, believing that it was the adopted method of his *confrères* but found it was not. He regards abortion as a pathologic condition from the beginning, and deals with it promptly. He referred particularly to cases up to the third month, where in the majority of cases, the decidua remained and interfered with involution of the uterus, the uterus remaining hard and heavy. In such cases more or less damage was done to the uterus and to the woman. This was the source of many displacements and of chronic lesions of the uterus and its adnexa. He could not let the opportunity pass without cautioning those engaged in the practice of obstetrics, and in general work, not to trust to nature in this class of cases. His manner of dealing with them was similar to that mentioned by Dr. Peterson. He makes an important procedure of it, believes that it should be done deliberately and under strict antiseptic precautions, every little detail being carried out with exactness. The curette was a safe instrument if properly used. After thorough inspection and cleansing out of the uterine cavity, he uses a strong application of carbolic acid and iodine, so that if shreds of secundines are left they will be destroyed by the cauterizing effect of the acid. The uterus is then packed with iodoform wicking, leaving its lower section rather loosely packed

with a single strand or so extending through the cervix, inasmuch as we desire drainage and the stimulating effect of the tampon in the uterine cavity.

Dr. STAHL in closing, said the same objection could be urged against the introduction of the hand in forceps extraction or in turning, or in extraction of the placenta after mature labor. Physicians did not hesitate to enter the uterine cavity with their finger in such cases. Furthermore, in doing hysterectomy, the surgeon did not hesitate to enter the uterus with his finger, and it seemed to him that there was as much objection to doing this as there was in using the finger in cases of abortion. His results had been very favorable following the use of laminaria tents.

SELECTIONS.

The Plague-Spots of Bombay: the "Chawls" of the Native Sections.—In the London *Lancet* (February 26), we find an editorial review of some of the recent official investigations regarding the plague in Bombay. It refers to one reported condition that is comparatively new, namely "that the important factors to be remembered were the filthy and insanitary chawls" which are inhabited by 70 per cent. of the population of Bombay. These "chawls" are mostly great tenement buildings, many of them from five to seven stories high, built on the flat system. Through the length of each flat runs a corridor, the interior of which is dark and unventilated, in which are situated latrines and out of which open on either side the doors of the numerous tenements. The rooms are about 8 by 12 feet in area, and each one is generally occupied by from six to eight persons or even more. So crowded are these chawls on any given area that window openings in respective blocks look one into another; they are therefore commonly kept covered, and apart even from this the rooms are so dark that, according to one inspector, artificial light had to be used in them by day. Between two rows of chawls is a species of back passage into which the inhabitants throw filth from the floors of the chawls, each of which is referred to as often containing from 500 to 1200 inhabitants, and these passages, it is said, are rarely scavenged. It is also pointed out that these chawls were erected to meet the demands of the cotton industry, and hence they are the outcome, not of native ignorance, but of Western civilization so-called. The same reporter estimates that the overcrowding due to these chawls is three times worse than anything that could be found in London, and his astonishment was, not that plague had become epidemic in Bombay, but that the disease had not carried away half the population. Sir Richard Thorne has emphasized the fact that the influence of soil in its widest sense was one of the first considerations to be held in view as regards a filth disease, such as plague, and he has pointed out that these chawls afforded precisely the soil needed for the maintenance of the epidemic. Even ordinary garden soil teems with micro-organic life, and pathogenic organisms find in soil a favorable medium for life and multiplication. One point only did he appear in any way to criticize in a certain official paper recently published, namely, the assertion that anxiety must remain unless science can suggest some effective means of eradicating the plague bacillus. As to this he contended that there were times when the appeal should be to practice rather than to science, and that so long as the chawls of Bombay remained what they are it was of no use to call upon experts or to wait for advance in science. Although it is doubtless a mistake to believe that the great fire of London freed that metropolis from its plague, yet, if medical considerations were alone in question, the destruction by fire of the chawls of Bombay would, he insisted, in the long run end in gain. "So, also, as regards the eradication of the plague bacillus, this is not what is wanted; it is rather the removal of conditions which enable an accidentally imported specific organism to multiply and spread. Action on this principle has all along been our English practice. We are prepared

to receive any number of vessels from western ports of India; we never propose to quarantine them lest they should carry plague bacilli; but we aim at receiving those vessels under conditions which are inimic to foreign pathogenic organisms."

Neuroses of Gout.—In a paper upon this subject presented to the Mississippi Valley Medical Association, Dr. L. Harrison Mettler of Chicago takes the position that the uric acid is not the cause of the familiar nervous manifestations of gout. He states that in the main, there are three general theories in regard to these neuroses. The followers of Haig believe that they are due to uric acid in the blood (chemic theory). Others think that they, as well as true gout itself, are but expressions of a neurotic diathesis (neurotic theory). Still others, with whom the author places himself, hold the view that a nervous taint, acquired or inherited, is the essential cause for gout and all the gouty manifestations; whereas these manifestations may be enhanced or made to assume variable characteristics by the auto-intoxication which is itself a result of the faulty metabolism produced by the original faulty innervation. With Cullen and Duckworth, therefore, he maintains that the gouty manifestations primarily are the result of a trophoneurosis. Faulty innervation, inherited or acquired, deranges the metabolic functions of the tissues, certain toxic excrementitious products are over-elaborated or uneliminated, and these reacting again upon the various nervous apparatus give rise to the said neuroses. These excrementitious products, as seen in the urinary alloxuric substances, consist of uric acid in combination with certain xanthin bases. In the gouty state the uric acid is frequently diminished in amount, but the increase of the xanthins explains the total increase of the alloxuric substances. With Kolisch and some other investigators, the author believes that the retention of the xanthins, rather than of the uric acid, is responsible for the general symptoms of gout. The uric acid which is now known to be formed only in the kidney and when found in the blood is reabsorbed from that organ, enters into combination in the blood to form the biurate of soda which for some unexplainable reason is deposited in the joints. The symptoms of lithemia and of certain forms of neurasthenia are also due to the retained xanthins and not to the uric acid. Hence neurasthenia, lithemia and gout have many features in common, auto-intoxication being the chief. The uric acid is significant only in one of these, namely, true gout, in which it goes toward the formation of the arthritic deposits. The retained toxins, especially the xanthins, are responsible for the general complexus of symptoms characteristic of all three diseases.

Upon this theory it is an easier matter to explain the numerous bizarre features of these three sets of diseases and to account for the variableness of the results oftentimes obtained from similar treatment in apparently similar cases. In elaborating these ideas in the early half of this paper Dr. Mettler refers to some of the more recent studies upon uric acid, quoting largely from Fitcher, Neusser, Kolisch and others. Cases were then cited to illustrate the neurotic nature of the diseases in question and the extreme difficulty of deciding whether the neurotic constitution is the cause or the result of the so-called lithemic state. In the case of the 12 year-old child the lithemic condition was especially pronounced and its amelioration naturally ameliorated the neurotic manifestations, nevertheless there was a marked neurotic inheritance and there is every evidence that this underlying vicious nervous apparatus was the primary cause of both the lithemic and neurotic manifestations. The latter half of the author's paper enumerates some of the principal neuroses associated with the gouty diathesis. Among these neuroses the author has seen cephalalgia, epilepsy, cardiac arrhythmia, chorea, convulsions, vertigo, pain including neuralgia and psychic pain or mental depression, hysteria, exophthalmic goiter, asthma, nervous dyspepsia,

diabetes, facial paralysis, multiple neuritis and sciatica, cerebral apoplexy and aphasia. The aphasia case referred to was especially pronounced. In a case of nervous prostration on the road to recovery an acute attack of rheumatoid arthritis in the right shoulder suddenly supervened. As the rheumatic pains were about to subside under the vigorous use of the salicylates, distinct amnesic aphasia occurred for three days. There was complete loss of the names of things (nouns) so that the patient would begin a sentence with one or two simple words and then suddenly stop with evident dissatisfaction at her inability to speak. With this there were slight delusions and illusions and such hallucinations as the hearing of footsteps and bells that did not exist. It could not have been the medicines employed that gave rise to these manifestations, for though the treatment was continued the aphasia, etc., terminated gradually the third day.

It will then be seen that the author agrees with Haig and Munchison in assigning lithemia as a cause of many neuroses, but he differs from them in giving credit to the retained xanthis rather than to the uric acid.

PRACTICAL NOTES.

Artificial Menopause Induced by the Snegirev Steam Treatment of Menorrhagia.—Baruch reports a case of severe menorrhagia promptly cured with the steam treatment, but followed by the symptoms of the menopause, although the patient was quite young, 11-para; eighteen months later the uterus was found hard and small, the fundus adherent and retroverted, the cervical canal completely obliterated.—*Sem. Méd.*, February 9.

Electrotherapeutic Treatment of Painful Fissure of the Anus.—The *Bull. de la Soc. d'Electrotherap.* for February, contains a detailed description of the remarkable cures effected by Professor Doumer in eleven cases of extremely painful fissures with obstinate constipation and hemorrhoids, with from two to four local treatments with the "high frequency" current. Relief was immediate, the sphincter algia diminished, the fissures healed over and the constipation and hemorrhoids subsided.

Treatment of Impetigo with Franklinization.—Fourteen cases rapidly cured with "electric effluvia" are reported by Doumer and Levezier of Lille, all children from six months to 12 years of age, accompanied by marked improvement in the appetite and health. The seances were repeated three times a week, lasting ten minutes each time, two to eight being generally required, and a machine powerful enough to emit sparks eight centimeters in length.—*Sem. Méd.*, February 9.

Thallium Acetate in the Night Sweats of Phthisis.—Combemale has obtained fine results with a single pill containing ten centigrams of thallium acetate administered about an hour before the sweats usually appear. The effect is quite lasting, and the drug must not be given longer than four days at a time, with an interval of eight days before commencing again. The chief accident observed from its use was a sudden alopecia, which requires supervision.—*Prog. Méd.*, February 26.

Treatment of Professional Eczema of the Fingers.—Edleson has been very successful for years with the following solution, with which the hands are painted once or twice a day and gloves worn for a while: Metallic iodine 10 centigrams, potassium iodide 25 centigrams, glycerin 12.5 grams. Especially effective in curing eczema due to repeated contact with water. Rózsás states that the direct application of lunar caustic after moistening the parts, will cure rebellious cases of professional eczema, the excess neutralized in a few moments with salt solution and after being wiped dry, the following salve applied: Salicylic acid 2 grams, zinc oxide and talc powder 24 grams, and yellow vaselin 50 grams. For external use.—*Sem. Méd.*, February 9.

Contagion of Chancre by Caustic Pencil.—A healthy 12-year-old lad, son of healthy parents, was treated for a polyp in the right nostril by a physician who cauterized it a few times with molded nitrate of silver, which in this case fully deserved the name bestowed upon it by the Germans, "hell-stone," as its use was followed by typical syphilitic infection, soon destroying the tip of the nose, nostrils and septum, when its course was arrested by antisyphilitic treatment.—*Deutsche Med. Woch.*, February 10.

Perpetually Sterile Bandage Box.—The bandage roll is placed in a small metal box with tight fitting metal cover. Between box and cover there is a narrow slit through which the end of the bandage emerges like the tape in a winding tape-measure. No space is left around the bandage strip, which pulls out with moderate effort. The protruding piece is cut off and thrown away, and the following portion of the bandage is found permanently sterile, as no bacteria can find their way into the air-tight box, which does not require to be opened until the last scrap of the bandage roll has been used up.—*Deu. Med. Woch.*, March 3.

Dangers of Artificial Respiration.—Brosch has described a case of sudden death in which artificial respiration was practiced, and at the necropsy the bronchi were found filled with the contents of the stomach. This can be easily accomplished in the cadaver, and is possible in the limp condition of drowning persons. To avoid all danger from this source, M. Buch advises first wiping out the mouth with the finger wrapped in a cloth, and then in the course of the artificial respiration avoiding all pressure on the stomach, confining the efforts to lateral pressure.—*Deu. Med. Woch.*, March 3.

Iodin Injections for Malarial Hypertrophied Spleen.—Parona considers hypodermic injections of the following solution the simplest and most effective treatment for hypertrophied spleen of malarial origin at our disposal to date. Metallic iodine, 25 centigrams; potassium iodide and guaiac 2.5 grams; pure sterilized glycerin, 25 grams. Inject one gram in the flank or back, the patient remaining in bed during treatment, suspending it as the organism becomes saturated with iodine. Four cases of enormous tumefaction of the spleen are reported practically cured, although one case required splenectomy later, on account of the mobility of the organ.—*Sem. Méd.*, February 9.

Rapid Process of Double Staining the Blood.—A drop of the blood is placed on a cover-glass and with it a drop of simple sterilized bouillon, then mixed together with the platinum loop, first passed through the flame and cooled. The mixture is dried and fixed over an alcohol lamp, in less than a minute, the cover-glass placed on a glass slide to protect it from the direct action of the flame. He then stains with eosin and then with methyl blue; the entire technique requiring scarcely five minutes.—*Cron. Med. quir. de la Habana*, xxiii, 23; *Sem. Méd.*, February 26.

Hernias During Pregnancy and Parturition.—H. Fischer has been studying the twenty-four cases on record with eight of his own, and confirms the general assumption that severe hernias under such circumstances are particularly troublesome, although the usual rest, etc., of the women favors the cure of slight pre-existing hernias. He has seen two cases of femoral hernia entirely cured with an English truss and the reclining position during pregnancy, and also cases of umbilical hernia held with strips of plaster, over which a good fitting bandage was worn. He does not believe in postponing a necessary operation on account of the pregnancy or child-bed, but advises an immediate operation after delivery, without waiting for the collapse from incarceration to supplement the operation shock, always using the Schleich method on account of the danger from vomiting after general narcosis, which produced abortion and death in one of his pregnant cases.—*Deutsche Med. Woch.*, March 3.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	\$5.00
Foreign Postage	1.75
Single Copies	10 Cents.

In requesting change of address, give *old* as well as new location.
Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newsum, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, APRIL 9, 1898.

THE ASSOCIATION OF THE MILITARY SURGEONS OF
THE UNITED STATES.

The events of the day are the strongest possible indorsement of the necessity for such an organization as that of the Association of Military Surgeons of the United States. In fact, the medical officers of the various branches of the military and naval services of the country are not associated as they should be, or in any way, officially or nominally, in one harmonious whole. The enthusiastic founders of this body, first and foremost among whom was our own illustrious NICHOLAS SENN—then Surgeon-General of Wisconsin, and now, and for long, we hope, Surgeon-General of Illinois—wisely foresaw that military surgery could not attain its highest development if left to the haphazard methods of independent and inexperienced individuals, and they instituted this Association for the improvement of military surgery, and it is evident that this can only be accomplished when the medical departments of every branch of the national defence shall have common methods of operation and interchangeable apparatus and personnel. While the army and navy are the right and left arms of this national defence, it must be borne in mind that the National Guard is the head, trunk and legs, and even though the arms and legs may be lusty and strong, can this be said of the other parts of the military medical body? Is it not the fact that in most of the States of the Union there is no such thing as a medical department of the National Guard?

In every State, it is true, there is a Surgeon-General, who is presupposedly the head of such a department as the Surgeon-General of the Army is chief of

the medical corps of the Army, and a Surgeon-General of the Navy, who is the chief of the bureau of medicine and surgery of the Navy Department, but is the Surgeon-General of Maryland, or Virginia, or Ohio, or Georgia ever titular head of the medical department of the National Guard of these States? Is he not really only an ornamental member of the staff of the Governor of the State, appointed by the incumbent of that office without regard to eminent qualifications or previous service and experience, and holding his position only during the gubernatorial term? Has he any official relationship, control or authority over the medical officers of the National Guard of the State? If he is not such a chief or head is it not because there is no department of which he can be chief?

A medical director in a certain important State of the Union, whose title to the medical directorship arose only from his being the senior medical officer of a brigade, when asked concerning his preparations for active service in the event of the brigade being called into service, as had actually twice happened, explained that he had an arrangement with an apothecary in the city of his residence, who engaged to supply him with such stores and appliances as he thought he might require. There was no State medical purveyor's office, no central depot of ambulances, no bureau of supplies of surgical and medical equipments, no organized hospital corps and no field hospital appointments: and what is true of this State is true of most others.

The Association of Military Surgeons of the United States is aiming to remedy these lamentable deficiencies by inducing the organization of a medical department in the National Guard of each State upon a uniform basis with the medical department of the Army and Navy, having (1) a *personnel* in which admission shall be gained only after a rigid physical and professional examination as assistant surgeon (or better, junior surgeon, for the title assistant is considered a misnomer in the national services) with assured promotion based upon merit and length of service from the lower to the higher grades, the Surgeon-General being selected for his eminent fitness from the medical directors or brigade medical officers and to be the head of a corps in which all the officers are associated and related as parts of a military whole; with (2) an organized *hospital corps*, enlisted and drilled for field service especially; and with (3) a central *depot of supplies*, including ambulances, field (skeleton) hospitals, surgical apparatus and appliances and medical stores, for issue and distribution on approved requisitions.

The advantages, and in fact, absolute necessity for such a uniform system are self-evident, and just as the title, National Guard, implies a community of purpose, its medical department should be in all respects and in every State one and the same, the State initials, like the letters U. S. A. and U. S. N., alone indi-

cating local relations as to source, responsibility and immediate control. It is to be hoped, therefore, that the appeal of the President and Secretary of the Association of Military Surgeons to the governors of the several States to send officially delegated representatives to the annual meeting at Kansas City on June 1, may meet with a general response, inasmuch as the occurrences of this year have demonstrated the need for just the objects the Association aims to accomplish. It is fortunate that the several special committees appointed at the Columbus meeting last year, to consider these questions of uniformity of organization and methods, are expected to report and from the high character and experience of the chairman and members of these committees, it may be expected that something definite may be evolved which will not only be of interest and value to all the States represented, but may result in the establishment of a well-organized and well-equipped and outfitted medical department all over the United States, rendering unnecessary in future cases of hostile operations the philanthropic assistance of sanitary commissions, Christian aid societies and other volunteer bodies. The axiom that there can be no efficient military establishment without a properly organized medical department was never better illustrated than in the recent wretched Greek fiasco, which was an object lesson of the helplessness of an army in which a medical department was considered a mere civil appendage, if, in fact, it was given any consideration.

THE DECREASING FREQUENCY OF TYPHOID FEVER.

There is perhaps no subject more interesting to the devotee of hygiene or the practical physician than the study of the frequency and mortality of diseases which occur with such constancy that all persons in all sections of the country are liable to be affected by them. It is a well recognized fact today that several of the great endemic and epidemic diseases of earlier centuries are decreasing in frequency and virulence and this decrease is of course largely due to the maintenance of strict modern quarantine, better knowledge of the means by which diseases are spread, and the institution of proper regulations controlling the individual who is afflicted. Other diseases more chronic in character, producing grave ravages throughout the human race by slower progress, as for example syphilis, are also known to be decreasing in frequency and virulence, and physicians of many years experience are constantly remarking upon the fact that syphilis in its malignant forms is rarely met with, at least as compared to its frequency twenty or thirty years ago. This decrease in syphilis is partly due to the fact that physicians understand the methods that should be used in combatting it far better than they did in the early part of the century, and, again, the

pharmaceutic fraternity working in league with chemists have produced preparations of the great specifics for these diseases in such forms that they can be readily administered and utilized by the physician in a manner which is impossible with crude pharmaceutic products. It is true that the "great white plague," tuberculosis, still reaps its harvest with a frequency and constancy which is most disheartening to those who come frequently in contact with it. But one disease of more rapid course as a rule, which has had a high mortality in the past, and to which all persons are subject with a certain degree of constancy, is typhoid fever. There is no doubt whatever that this disease is decreasing in its frequency, its virulence, and consequently in its mortality in nearly every portion of the civilized world. It is unfortunately only too true that it is almost endemic in most of the large cities of the world. But at the same time the number of cases which are affected by it are diminishing in a manner which is almost startling. Less than fifty years ago it was commonly recognized that the mortality of typhoid fever was about 25 per cent.; whereas it is evident now that the mortality varies from 10 to 15 per cent., and in those portions of the world where good drainage and a pure water supply have been provided to the inhabitants of cities, this mortality has been still further decreased, until it is below that which used to be obtained in hospitals in which the very best and most enlightened treatment was carried out. In one of the "Systems of Medicine" which has been recently published, Mosny is quoted as showing that the death rate of Vienna decreased from 12.05 per 10,000 to 1.1 after a pure water-supply was provided that city, and a similar decrease has also taken place in Dantzic. In Stockholm a somewhat similar fall is shown by the statistics of that city.

In Munich the mortality has fallen from 334 per 100,000 inhabitants in 1858, the highest mortality which that city has had during the last fifty years, to 3.4 per 100,000 inhabitants in 1896. In London the last twenty years has seen a drop from 267 deaths in the million to 161. In Manchester from 450 in the million to 250, and in the whole of England the death rate has decreased from 1228 per million in 1838 to 137 per million in 1892, and this in face of the fact that the rules of health boards in regard to the notification of diseases are maintained and obeyed better and better as each year goes by, and that the training of physicians and the increasing aids to diagnosis, probably result in the reporting of more cases of obscure typhoid than have ever been reported before.

BILLINGS tells us that in Norway from 1888 to 1891 the mortality was less than 10 per cent. In the present Maidstone epidemic in England it is 8.5, and in France it has fallen from 21.5 to 13.5 per cent.

In our own country the mortality of this disease has decreased in Boston during the last fifty years

one-third: in Philadelphia one-third and in New York almost one-half.

Naturally we would expect from this showing that the frequency of the disease would probably be very much decreased, and this is shown in the health records of a number of the cities which keep sufficiently careful records to afford us valuable information in this respect. In New York and Philadelphia, for example, the frequency has decreased almost one-half, and an examination of a number of individual hospital records shows a corresponding improvement.

The next question which arises, is to what is this much desired result to be ascribed? Is it that the present generation are gradually becoming immune to a disease which has seriously affected their forefathers, or that medical skill has improved to such an extent as to cause this vast improvement in life-saving, or, finally, are we to attribute these beneficent changes to a diffusion of knowledge in regard to the means by which this malady is spread, a diffusion which has been as necessary amongst the body of the profession as it has been amongst the laity, both of which classes are at the present time beginning to realize to the fullest extent the amount of pain and suffering and death which can be put aside by the use of even moderately severe measures looking toward the disinfection of discharges, the avoidance of the contamination of water-supplies by the sewage and the carrying out of those simple rules of hygiene with which even the poorest should be familiar. Admitting that the first two possible causes are exciting factors in producing the results which we have named, it is an undeniable fact that to the hygienists belongs the credit for the marked changes which have occurred. Immunity acquired through heredity is theoretically beautiful to contemplate, but practically scientific analysis and the best informed physicians are willing to admit that while a certain number of lives are saved by the employment of rational methods in the treatment of enteric fever no such decrease in mortality as has occurred can be attributed to improved therapeutics. Some one has well said that every death from typhoid is a case of homicide, for undoubtedly it has been proved by bacteriologic research and by frequent experiment upon enormous bodies of people that each case of typhoid could have been avoided by proper disinfection of the discharge of a patient who has disseminated the poison, by proper treatment of the ingesta taken by the individual. Under these circumstances it is evident that physicians should not only use ordinary means to destroy the bacillus of Eberth in every case of typhoid fever to which they are called, but that they should impress by every means in their power upon their patients and upon the popular officials the necessity for preventing this disease by means which are so easily carried out, and so blessed in their results that he who ignores them is guilty of the gravest sort of mistake.

MIGRAINE AND EPILEPSY.

The pathologic etiology of migraine has been long enough the subject of speculation, but we are still in the phase of conjecture or at least theory: our positive acquisitions of knowledge as to the essential pathologic process are so far practically nothing. The notion that it is a vasomotor neurosis has been largely abandoned, and neurologists at the present time are inclined to class it with epilepsy as a fulgurant cortical neurosis, a symptom of cortical instability associated, it may be, with some conditions of morbid metabolism, such as the uric acid or arthritic diatheses. While it may be assumed that it is a derangement to some extent of the function of the sensory cortical elements due to various irritations arising from the digestive organs, the sexual apparatus, the general or spinal sensory tracts, etc., etc., its ultimate cause must be looked for somewhere back of all these in some more profound systemic condition, the exact nature of which we are only able to conjecture at the present time.

Dr. B. K. RACHFORD, who has, during the past few years, advocated the theory of leucomain poison as the essential cause of this disorder, publishes in the April issue of the *American Journal of Medical Sciences*, a further paper on the subject reiterating his former views and supporting them by additional arguments and facts. His former findings of xanthin and paraxanthin in the urine of sufferers from migraine, have, he states, been confirmed by continued observations during the past two years, especially as regards the latter. In normal urine paraxanthin is present in too minute a quantity to be readily detected, and this is true also of that secreted in ordinary attacks of headache, which have not the clinical features of what we recognize as migraine. He does not, therefore, believe that cephalalgia is itself necessarily or directly associated with this excess of paraxanthin; it is the special condition that gives rise to the peculiar migrainous attack. An over-production and accumulation of this product in the blood from some recondite neurotic condition appears to be his theory, and the migrainous explosion is the attendant of its periodical excretion. It is the most toxic of all the leucomains of the uric acid group, and some of the symptoms it produces are suggestive of those of migraine. From all the data thus far obtained, Dr. RACHFORD deems it reasonable to assume that paraxanthin is to be considered as an important factor, at least in the production of true migraine.

The relations of epilepsy and migraine suggested in the theory stated as just now prevalent, are quite strongly suggested by certain clinical facts familiar to neurologists and to whoever has any extensive experience with these neuroses. Epileptiform migraine with loss of consciousness, more or less complete, in some of the attacks, and even with convulsive manifestations, is a well known condition, and the disorder has

unquestionably a close relation with the more formidable affection, as do also certain forms of vertiginous attacks, themselves apparently related to migraine. The pathology of epilepsy, considered as a disease of itself, is also obscure, but when it is reckoned only as a symptom of various pathologic states it is possibly more comprehensible, or at least more easily explained in a theoretic way. Dr. RACHFORD makes this point in his paper and indicates the distinctions between organic or mechanical, reflex and toxic epilepsies, the first being readily comprehensible, the second due to lack of inhibition from defective development due to inheritance or malnutrition, and the last as yet imperfectly understood, but probably not the least in importance of the three general types. As a special form of toxic epilepsy he recognizes that from paraxanthin intoxication, which according to his investigations forms a small but appreciable proportion of the whole class, and has some special features of its own, though hardly enough to characterize it clinically as a definitely marked type. It is more common in women than in men, in middle than in early life, and always in cases that have suffered from, or are still subject to, migraine, thus indicating clearly the common causal factor. It is compatible with unimpaired intellectual powers, thus differing from most of the other forms of epilepsy, and is generally more amenable to treatment, thus rendering an early diagnosis the more important.

It would appear from the facts that RACHFORD has collected that there is a common cause in certain cases of epilepsy and of migraine, and that, as he is inclined to believe, this is to be found in the toxic action of certain leucomains of which paraxanthin is probably the most important. That these do not invariably cause epilepsy or migraine may be admitted, but that is one of the very common facts for which we can have as yet no explanation, and which does not vitiate the conclusion that there is sometimes a causal relation between their occurrence and that of these disorders.

There are undoubtedly other autotoxic factors in epilepsy, those, for example, from the intestinal organs, and the analogy of drug epilepsies is sufficient to make this probable. It is an interesting fact, none the less that we can in this way find a plausible explanation of the long recognized affinities of migraine and epilepsy, and the line of investigation here indicated is well worthy of being further followed out. It may throw light not only on the causes but also on the essential lesions and the practical questions of treatment and prophylaxis.

THE CARDIO-VASCULAR SYSTEM AND ITS RELATIONS TO DISEASE.

A well-known clinician of wide experience in scientific medical societies once remarked that the two

most active societies devoted to the study of pathology were to be found in London and Philadelphia. Whether this be true or not matters little, provided either of these bodies provides the general profession from time to time with the results of their studies in such a form that there is direct benefit to physician and patient. Such a function we think was performed by the Philadelphia Pathological Society when at a recent meeting, it devoted its attention to the presentation of a symposium on the "Pathology of Diseases of the Cardio-vascular System," which contained contributions upon the pathology and morbid anatomy of the heart, vessels and blood. Perhaps the most interesting of these papers was that of PACKARD, who dealt with vascular changes and who pointed out ("Transactions of the Philadelphia Pathological Society," March 15, 1898) that not only do we grow old in proportion to our vascular changes but that arteries are vessels which are not only subjected to insults from the exterior but also very often have to carry blood which is capable of exercising harmful effects either from its chemic characteristics or by reason of its containing bacteriologic infections. PACKARD calls attention also to several communications, made recently to medical literature, which he thinks indicate that the endarterium is perhaps equally susceptible with the endocardium to infectious processes or at least inflammatory changes. In the *Bulletin et Mém. de la Soc. Méd. des Hôpitaux*, for Oct. 28, 1898, THOINOT and GRIFFON reported a case of a woman of 53 years who suffered from several attacks of erysipelas of moderate local severity, but severe systemic manifestations from which she eventually died some weeks after the last admittance to the hospital. The autopsy showed old and new lesions in the aorta, the latter being composed of fibrinous, gelatinous deposits of amber-yellow material slightly elevated above the aortic surface. These plaques were formed essentially of a fibrillary substance running parallel to the axis of the vessel, and masses of cells penetrated the internal coat of the vessel as if arranged about a blood vessel. Further the degenerative processes extruded into the media and adventitia, in which near the changes in the intima were areas of intense inflammation. In another instance, recorded in an abstract in the *Gaz. hebdomadaire de Méd. et de Chir.*, Oct. 8, 1897, by ISELIN, a man of 54 years, after exertion, was seized with pain at the base of the neck and severe dyspnea. Death came suddenly and a clot was found plugging the left subclavian artery, and the entire thoracic aorta was the seat of acute aortitis with great thickening. There were no other morbid changes elsewhere save early tuberculosis at the apices of both lungs. Then again we may quote the experimental studies of BOINET and ROMARY (*Arch. de Méd. expérimentale et d'Anatom. pathologique*, 1897, p. 902). These observers injected various micro-organisms into

the blood stream and thereby caused aortitis after producing aseptic trauma of the intima. They found that Eberth's bacillus, the bacillus coli communis and streptococci all caused aortitis when so injected, nor did they stop here but also discovered that anthrax bacilli and tubercle bacilli produced similar effects, as did also those of tetanus and diphtheria. Again the toxins of diphtheria, of streptococci and of the bacillus of tuberculosis, when injected caused aortitis, as did that of cholera. Various metallic poisons did likewise.

These instances combined with three cases examined in which human beings were the victims of infection seem to prove very conclusively that PACKARD'S belief in the susceptibility of the endarterium is correct and, if more evidence be needed to prove the fact, we find LEVY (*Archives*, as already quoted for 1896), recording a case in which a grayish tubercle was found in the subendothelial layer of the aorta, and STROEBE (abstract in the *Centralblatt für Allg. Path. und Path. Anat.*, Nov. 1, 1897) reporting the case of a boy, with general miliary tuberculosis, who had a caseating polyp of a tubercular nature in his ascending aorta. Still further proofs are found in the case of a burned child mentioned by HOLLIS, whose aorta was found at the postmortem to be the seat of early atheroma. It is evident that endarterial disease is still, comparatively speaking, an unexplored field, and that it offers one of the most interesting sources from which we can gather new ideas as to the pathology of vascular changes and the perversions of nutrition depending upon them.

CHARAKA-SAMHITA.

We have received fasciculi 17 and 18 of the Charaka-Samhita, translated into English by AVINASH CHANDRA KAVIRANTA, Calcutta, which is the Hindu medical work corresponding to the Hippocratic treatises. (See JOURNAL, Vol. XXI, p. 465.) Section 17 contains a continuation of lessons 5, 6 and 7, which are aphoristic utterances on the body and medicines, including food and drink. In the 18th fasciculus we find less of how diseases are to be conquered by the physician, and first he says: "If an intelligent man, who knows the difficulty, the lightness of all acts, the results, immediate and remote, of acts, and place and time, desires, impelled by proper reasons, to become a physician, he should then, at the outset, select the particular treatise he should take up for study. Divers treatises pertaining to the profession of the physician are in circulation;" and, after a eulogy of the Rishi, a very ancient work, he describes the qualifications of the preceptor, which, he says, should be: "He should be one whose doubts have all been cleared in respect to medical scriptures. He should be possessed of experience. He should be clever. He should be compassionate toward those who approach him. He should

be of pure conduct. He should have a practiced hand. He should have all the implements of his profession. He should have all the organs of sense. He should be conversant with the nature of health, of disease, of medicaments, of time, of place, of man, etc. He should be conversant with the tendencies and acts of the healthy and of the diseased. He should be one whose knowledge of the medical science has been supplemented by a knowledge of other branches of study. He should be without malice. He should be without a wrathful disposition. He should be capable of bearing privations and pain. He should be one well affected toward disciples and disposed to teach them. He should be capable of communicating his ideas. A preceptor possessed of these qualifications very soon succeeds in equipping an intelligent disciple for the requisite characteristics of a physician; like a cloud belonging to the proper season, equipping a fertile field for an abundant harvest. Approaching such a preceptor, a pupil desirous of quoting him, should attend on him with heedfulness like one revering one's sacrificial fire, or one's deity, or one's king, or one's father, or one's patron. Then study the entire treatise through his grace. The pupil should duly strive to comprehend the relations of the different parts toward one another and of each part toward the whole: to understand the consistency and correlation of the words employed to apprehend the sense of the author and to acquire facility of exposition."

The means for achieving these ends are, as follows: "Study, teaching and conversations.

"The following is the method to be observed in study in health and observance of the rule regarding time: The pupil should rise at daybreak or a little before, going through the necessary morning rites, performing his ablutions and bowing under the deities, the Rishis, the cow, the preceptors, those venerable for age, those that have been crowned with success, and professors. Then, seating himself down at his ease on a level and clean spot of ground, he should repeatedly cite the aphorisms in due order with his mind set on the recitation."

CHARAKA advises the preceptor, who will set his mind on teaching, to examine the person that presents himself for becoming a pupil. The disciple should be as follows: "He should be of mild disposition: noble by stature; not mean in acts. His eyes, mouth and nasal lines should be straight. His tongue should be thin, red and unslimy; his teeth and lips should have no deformity. He should not have a nasal voice. He should be possessed of intelligence: free from pride, with a large understanding, power of judgment and memory, and a liberal mind. He should belong to a family the members of which have studied medical scriptures, or followed medicine as a profession. He should have a devotion for truth: his senses per-

fect; free from haughtiness, disposed for solitude, and a thoughtful disposition. He should not be defective in respect to any limb. He should be free from wrath, fond of study, devotedly attached to both theory and practice; free from cupidity, without sloth, and should be endowed with excellent character, purity of behavior, devotion, cleverness, compassion for all; should seek the good of all creatures, and should be prepared to obey all the commands of his preceptor, to whom he should be attached. One adorned with such qualifications has been declared to be worthy of acceptance as a pupil."

We fear that some of our modern medical students would find it difficult to compete with the ancient Hindus in possession of these very moral attributes. This fasciculus is of very great interest not only to the medical historian, but to Hindu scholars in general.

THE WEEK IN CONGRESS.

With the exception of the rather tedious speech of Senator CAFFERY recommending his bill, sanitary matters received little attention. Estimate of deficiency in the appropriation of the Quarantine Service was received in the House and referred to the Committee on Appropriations. The naval appropriation bill is under consideration.

CORRESPONDENCE.

The Serum Treatment of Tuberculosis.

DENVER, COLO., March 29, 1898.

To the Editor:—I note in your last issue a criticism of my report of cases, published in the JOURNAL of March 19, by Kenneth W. Millican, M.D., B.A., M.R.C.S., which I feel deserves a reply. Dr. Millican states that antiphthisic serum T. R. (Fisch) "is recommended in the so-called pre-tubercular stage, in the first stage and the early part of the second stage prior to disintegration and in these alone." He criticises the report sharply, because all the cases were chronic cases and not applicable to serum treatment. The Doctor has forgotten that in the February 5 issue of the JOURNAL there appeared two articles on the treatment of tuberculosis with antiphthisic serum T. R., in which sixteen cases were reported, of which fourteen were chronic cases, having existed from one to eleven years, and yet no criticism was made on account of their not being appropriate cases. Why? Was it because the reports were more favorable?

It was because I believed that the deductions drawn from these cases were not justified that I reported my cases, feeling that not only the "truth, but the whole truth," should be recorded. I admit that in reporting these cases more could have been added in the way of detailed account of symptoms and physical signs, but in practicing brevity, which is the chief value of many papers, something may have been omitted that would have rendered the case clearer to the critical mind. Dr. Millican decides that all, except possibly one or two cases, were cases of mixed infection. In reply I would say that in only one case were streptococci found in addition to tubercle bacilli upon commencing treatment, and this was the only case accompanied by fever and other symptoms of mixed infection.

It is not only proven, but admitted, that the serum treatment is a failure in long-standing chronic cases of tuberculosis.

The question remaining is whether incipient or early cases will recover in spite of the remedy or whether it hastens recovery. As early cases invariably recover, and indeed many of the later cases, by proper climatic treatment it must therefore remain with our Eastern colleagues to solve this problem. I would, however, sound this warning far and near. Do not keep incipient cases on serum treatment until all chances of recovery from a change of climate has passed in perhaps the vain hope that they may be cured by this means. Test the serum treatment on those who can not make the sacrifice incident to a change of climate. All early cases that can possibly make the sacrifice send westward, until the full value of this treatment has been proven and you will never regret the results.

Very truly yours, F. E. WAXHAM, M.D.

Homing Pigeons as Medical Messengers.

ELIZABETH, ILL., March 31, 1898.

To the Editor:—For several years the undersigned has had under consideration homing pigeons as medical messengers. My correspondence with doctors who use them for this purpose, and also information obtained in medical journals and books bearing on the subject, so encouraged me that I was induced to invest in some of the "Belgian Homer" pigeons, and now have established a loft of aerial messengers as part of my equipment as a medical practitioner.

The young birds now under training encourage me to say to the JOURNAL readers that my expectations have not been dimmed, and I am convinced that if medical men will look into this matter, if they have not already done so, they too will find it feasible. In order to have the homer pigeon serve me in an efficient manner, I am having the entrance to the loft connected with electric bob-wires, so that when a bird returns home with a message from a patient, the alarm will be given at my office and residence, just as soon as the bird returns and is passing under the bob-wires into the loft.

Just inside the bob wires is a cage or box, placed in such a manner as to make the pigeon messenger a prisoner until the message is secured. Professor Marion of the U. S. Navy Academy has invented a capsule in which the message to be sent is placed, and then the capsule is fastened to the pigeon's leg.

The loft need not be expensive; a space in the barn eight by twelve feet and six feet high and about ten feet from the ground is room enough for thirty homing pigeons. If a special house is constructed, for want of room in the barn, the writer had constructed a loft as follows: Size, six by eight feet with eleven feet studding. Five feet from the ground a floor was placed, leaving the up stairs, or loft proper, six by eight by six feet. The down stairs is inclosed with poultry wire; the up stairs, first with tar paper, then ship lap. Trap doors through the floor permit the birds to come down to the ground, a much needed recreation for the old birds that can not be given their liberty, since they will leave you if an opportunity presents itself. It is the young birds hatched from your loft, or those you get when just old enough to ship (about six weeks old), that can be trained for messenger service, when three or four months old, by taking them several miles from their loft, east, west, north and south, and let them fly back home. This is to be repeated and each time the distance increased, until the remarkable distance of 100 to 1000 miles may be attained, at the rate, for the shorter distances, of an average speed of one mile per minute.

Fraternally,

PHILIP ARNOLD, M.D.

Strongylus Gigas. One More Case.

CHICAGO, March 30, 1898.

To the Editor:—Anent the report in the JOURNAL of March 26, my own observations may be of interest. In 1854, while

residing in St. Louis, early in the spring my husband, then an animated amateur huntsman, complained of sudden darting pains in the region of the kidneys. They would however not persist, but give way to a rather dull ache and come and go. Then at once he became chilled and felt very sick. Our physician pronounced it malaria, contracted on his hunting grounds in the so-called bottoms of Illinois opposite St. Louis. He and his friends had been in the habit of drinking the water of the brooklets in the bottoms, though "disinfected" by whisky, as they thought. Soon he became delirious, diarrhea and hemorrhage from the bladder set in, and consultation was obtained. The second doctor, an old resident of this country, pronounced it bilious fever of the worst form. Indeed, excessive hemorrhage from the bowels, bilious vomiting and high fever took his strength rapidly away. However, he pulled through, and as soon as he was able we removed him to the so-called "bluffs," near St. Louis, in Illinois. The people there had no other water than a strong sulphuretted well, and in the second week of our stay he complained of trouble in urinating, and after several efforts, passed a worm about five to six inches in length; in the course of several days, five or six more of various length. I immediately recognized them as *strongylus gigas*, well described in Aken's "Natural History," as occurring in the kidneys of animals. I had found them in swine kidneys before.

Did this parasite cause the whole affair? Did he drink the eggs with brook water? Did the sulphur water drive them off? Very likely; we never observed any after that.

Respectfully, ROSA H. ENGERT, M.D.

Concerning the Norway Lepers.

PARIS, March 19, 1898.

To the Editor:—In reply to Dr. Hansen's letter in the JOURNAL of February 26, I would say that I got my information as to the number of lepers in Norway from a guide book (I believe Murray's), which I thought at the time was reliable, but which it seems was not.

Now the information as to the other points in my letter, including the number of lepers that Dr. Hansen saw in America, and our profound ignorance, as a profession, of the whole subject of leprosy, I got from an attending physician in the Bergen hospital.

Up to this time, I did not know that Dr. Hansen had ever been in the United States, or that he was the eminent authority on this subject that he is.

I had before seen considerable of leprosy in the East, in its worst form, but it was only after I visited this leper hospital at Bergen that I appreciated the many different phases in which the disease may manifest itself. I am quite willing to classify myself among those who know very little about this terrible disease.

Yours truly, W. S. CALDWELL, M.D.

Anemias.

CINCINNATI, April 3, 1898.

To the Editor:—It was with pleasure that I read your editorial upon "The Differentiation of the Anemias," but as there was one statement that does not harmonize with my experience, I offer such in the form of a friendly scientific criticism.

You state that the megaloblast is diagnostic of pernicious anemia if it exceeds the normoblast in number. This statement is misleading, as is also your summary, for often we may have a pernicious anemia in which the differential count will not reveal a single megaloblast; when the *megaloblasts exceed the normoblasts the prognosis is fatal*.

Recently I made the examination of a case in which there were neither megaloblasts nor normoblasts found but the summary made the diagnosis. The examination revealed the following: Red, 1,200,000; white, 4,000; hemoglobin (Fleischl) 35 per cent.; color index 1.45.

Red cells: poikilocytosis, polychromatophilia.

WHITE CELLS.

Adult.—polymorph. neutrophiles, 33.8 (normal 60 to 70 per cent.)

Young.—(Large mononuclear 1.8, transitional 2.6, small mononuclear 59.4. Total, 63.8 (normal 20 to 30 per cent.)

Old.—(Eosinophiles) 1.8 (normal $\frac{1}{2}$ to 4 per cent.)

Myelocytes.—6 (normal only in bone marrow).

(The full report of this case appears in the transactions of the Academy of Medicine of Cincinnati published in the Cincinnati *Lancet-Clinic* of March 19, 1898.)

A proper summary for pernicious anemia should be as follows:

Red, 1,200,000 or less; white, less than 5,000; color index, high, above 1.00; poikilocytosis, polychromatophilia.

Increase of young white cells; decrease of adult white cells. Prognostic: Proportion of megaloblasts to normoblasts.

Respectfully yours,

W. EDWARDS SCHENCK, M.D.

Aut Rush Aut Nullus.

PITTSBURG, PA., March 28, 1898.

To the Editor:—Is it not possible to broaden "The Rush Monument" project into "A Monument to American Medicine?" Rush would still be the central figure, to which could be added medallions, or panels, honoring McDowell, Wells and Sims. It has been repeatedly urged that we are not as loyal to our profession as the homeopaths, who have erected such a fine monument to Hahnemann. But scientific medicine is not founded on any one man, no matter how great he may have been. I feel sure contributions would flow in faster if such a memorial to American medicine was contemplated. The three I have named made discoveries and instituted operations that have revolutionized surgery, and so, surely deserve a place on such a monument. The profession here have recently subscribed \$500 to the fund, but I have heard many doctors express a wish that the monument might be wider in its teachings.

Respectfully,

THOS. D. DAVIS, M.D.

Esophagostomy vs. Esophagotomy.

PHILADELPHIA, March 29, 1898.

To the Editor:—I find the remarks made by me in the discussion of Dr. Roe's paper in the issue of the JOURNAL (March 26, page 716), as reported, are so at variance with the idea that I wished to convey, that I hope you can find it possible to correct them. I distinctly said that *esophagostomy* is more desirable than *esophagotomy*, because the dangers of entering the posterior mediastinum are thus removed and we are enabled to remove the foreign body, if there be such, or divide the stricture through the external opening, thereby inflicting the minimum amount of force in the ulcerated region.

Yours faithfully,

L. J. HAMMOND, M.D.

Examining Committee Connecticut Medical Society.

NEW HAVEN, March 29, 1898.

To the Editor:—In your issue of the 26th inst., you give a list of the States that require an examination before a State board before admission to practice, but failed to mention Connecticut. You will see by a perusal of the enclosed copy of our State law that an amendment, approved by the Governor on May 25, 1897, provides that no one can now begin to practice medicine in this State without passing an examination before one of the examining committee, diploma or no diploma.

Very truly yours, MAX MAILHOUSE, M.D., Sec'y
Examining Committee of the Connecticut Medical Society.

PUBLIC HEALTH.

The Colored Race in Life Assurance.—The Atlanta University has examined into this subject and issued a pamphlet giving statistics of results. In general, the conclusions are as unfavorable as those that have formerly been made public. The prevailing causes are scrofulous, infantile and pulmonary diseases, the following comparison being from Richmond, Memphis and Charleston combined; by consumption and pneumonia the colored showed a rate of 75.5 as compared with white 32.8, being an excess of 130.5 nearly. In fevers, as typhoid, scarlet, malarial, etc., the excess was 30 per cent. on the same side; in cholera infantum, convulsions, etc., it was 165.1. Consumption and pneumonia thus appear the most deadly. As to the former alone, the percentage of excess of deaths per 10,000 in case of blacks over deaths of whites, covering periods of four years each, from 1881 to 1895, was from 143 to 172 in Atlanta, from 90 to 137 in Memphis, from 162 to 239 in Charleston, from 128 to 149 in Baltimore and from 87 to 114 in Richmond. This is an unhappy condition, but not necessarily a hopeless or even a discouraging one. The evolution of the long depressed race must be slow, but it is none the less sure under environments that are no more unfavorable than we know them to be in the area of this inquiry. The Prudential Company has had an experience in both equal and discriminated insurance for blacks and whites. For a term of years it has been in the habit of giving one-third less insurance, for the same money, to colored than to white "adults," or 12 to 70 years. During the period in question mortality was separated and tabulated by color and special search and study among health reports and census reports was made. From 1884 to 1893, inclusive, the company's experience showed an average loss per \$1000 at risk of \$16.96 among whites and \$21.63 among blacks. The causes were found to be four: Comparatively higher actual mortality resulting from lack of physical vigor, inherited tendencies to disease, neglect in sickness, improper food, unwholesome habits of life, unhealthy localities; a heavy lapse rate, in which the "selection" was against the company as usual: a low moral sense; ignorance of its attendant evils, although this last-named cause might seem included in the others. Even among the small number of negroes who are thrifty, intelligent and on a high comparative level of moral and social living the Prudential is satisfied that mortality still exceeds that of whites, owing to low vitality and inherited weaknesses of constitution. The Sun Life of Louisville has reported a similar experience and belief, adding that Southern whites object to joining any company which accepts negro risks freely, not from race prejudice, but because they do not believe insurance of the two races on equal terms to be equitable. The lowest of Northern laborers may possibly have as high a mortality as among the negroes, but no proof can be had because the mortality of the low Northern whites is inextricably merged in the general mortality. The negro lapse rate alone would make him an undesirable risk. The reporter of the company believes that the negro generally insures out of vanity and the love of novelty; the notion of a showy funeral impresses him, but wears off in time, when he is ready to drop out; he is with difficulty persuaded to revive an insurance, but readily consents to "join over," often proudly exhibiting as trophies a collection of policies.

The Limitations of Formaldehyde as a Disinfectant.—Dr. Harrington of the Harvard Medical School, recently undertook a series of experiments to ascertain the efficiency of formaldehyde as a disinfectant, its penetrating power under varying conditions and its action on higher organisms. His experiments show that while formaldehyde has extraordinary power as a surface disinfectant, greater than that of any other known substance, it is not absolutely thorough in all cases even as a surface disin-

fectant in room treatment. The penetrating power of the gas depends largely upon the conditions as to moisture. Through dry pervious substances, as cotton cloth, absorbent cotton, hair, etc., it appears to penetrate more or less easily, but not always in sufficient amount to exert germicidal action, as is shown by the results with the tube cultures and flasks of decolorized fuchsin, which were stoppered in exactly the same manner. In the presence of moisture the penetrating power is practically *nil*. The experiments can lead to but one conclusion, therefore, that formaldehyde must be regarded and employed as a surface disinfectant and can never be anything else, in spite of its power of penetration under favorable conditions. This conclusion is in accord with that of Aronson, Pfuhl, Nieman, Bosc, Roux and Trillat, and Vaillard and Lemoine. It has been asserted by a number of authors, among them Aronson, Pfuhl and Posenberg, that formaldehyde exerts no deleterious action on higher organisms. The results produced by the gas on the two rabbits used in the first experiment were sufficiently certain to demonstrate the falsity of this theory. The experience of several others, who are daily engaged in the work of house disinfection, has shown that animals such as dogs and cats that have accidentally been confined in rooms undergoing formaldehyde disinfection, rarely survive the operation when the latter is properly carried out. On the other hand, the experience of these same persons is that insects such as roaches, flies and bedbugs, are not much affected. His observations in this direction have been limited to the cases of occasional flies, and one dish of cockroaches, all of which were killed.—*American Therapist*, February.

NECROLOGY.

OLIVER ALBERT JUDSON, M.D., Jefferson, 1851, of Philadelphia, who has just died, was a volunteer surgeon during the war. He was a member of the Military Order of the Loyal Legion, the Sons of the Revolution, a Fellow of the College of Physicians, a member of the Academy of Natural Sciences, vice-president of the Pennsylvania Institution for the Instruction of the Blind, a manager of the Children's Hospital, a consulting physician at Blockley Hospital and a physician of the Philadelphia Dispensary and of the Howard Hospital.—*New York Tribune*.

GEORGE STEBBINS LITTLE, M.D., of Brooklyn, died March 30, in his 73d year, of capillary bronchitis and valvular disease. He was born in Middletown, N. Y., in January, 1826. He was graduated at the New York University school in 1848. He was assistant surgeon in the Nineteenth and Ninety-seventh Regiments, New York Volunteers, for nearly two years, and full surgeon of the latter troops until the muster-out at the close of the war. In 1864, he returned to Brooklyn and resumed medical practice. He was a member of the Kings County Medical Society and prominent in Grand Army matters. Since 1894 he had been an assistant sanitary inspector of Department of Health. He leaves a widow and one daughter and a son. His final illness was of about two weeks' duration.

MORTIMER A. R. F. CARR, M.D., Cumberland, Md., March 24, aged 68 years.—F. P. Carter, M.D., Wauwatosa, Wis., aged 26 years.—A. F. Henry, M.D., Alamo, Ind., March 29.—George T. Hough, M.D., New Bedford, Mass., March 24.—E. D. Lipscomb, M.D., New Market, Ala., March 29, aged 34 years.—Carpenter Weidler, M.D., Mechanicsburg, Pa., March 25, aged 70 years.—Hugh Hagan, M.D., Atlanta, Ga., March 22, aged 35 years.

DEATHS ABROAD.—Staff-Surgeon Gottfried Lenhartz, Editor of the *Deutsche militär-ärztlichen Zeitung*.—Max Dahmen, well known by a series of publications on bacteriology, and for many years director of a bacteriologic laboratory at Krefeld.—Franz Lörinczy, Editor of the *Közegészegügyi Kalausz*,

aged 52 years.—Carlos de Silóniz y Ortiz, Professor of Anatomy in the Medical Faculty of Barcelona since 1847.—Gayraud, sometime Agrégé Professor of Surgery in the Medical Faculty of Montpellier, a former President of the Montpellier Academy of Science and Letters, and author of several important articles in Dechambre's *Dictionnaire Encyclopédique des Sciences Médicales*.—Du Brueil, Physician to the hospitals of Rouen.—A. D'Ambrosio, Extraordinary Professor of Orthopedic Surgery in the Medical Faculty of Naples.

BOOK NOTICES.

The Surgical Complications and Sequels of Typhoid Fever. By Wm. W. KEEN, M.D., LL.D.; based upon tables of 1700 cases compiled by the author and by Thompson S. Westcott, M.D., with a chapter on the Ocular Complications of Typhoid Fever, by George E. de Schweinitz, A.M., M.D., and, as appendix, the Toner Lecture, No. 5. Philadelphia: W. B. Saunders, 1898. Pp. 386. Price \$3 net.

"The province of the physician and that of the surgeon," say the authors, "are in general sufficiently sharply defined and differentiated, yet they have many points of contact. While some diseases belong exclusively to the province of the one and some of them to the other, other diseases may fall with equal propriety under the care of either practitioner. Still another class of cases from the beginning, in the domain of medicine may terminate in that of surgery, and we may lack a very complete history from the very fact of this division of their care and interest. Among the diseases classed as strictly medical, none deserve the appellation more definitely than the continued fevers, especially typhoid fever; yet the present work shows that these fevers are not infrequently the cause of the gravest and least expected surgical troubles, mention of which is generally omitted even in our best text-books on medicine, still more rarely noticed in works on surgery, and where noticed, it is only with the greatest brevity."

The authors discuss the pathology of the disease, particularly the behavior of the typhoid bacilli outside and inside the human body, and the wide diffusion of typhoid bacilli in various organs and tissues of the body; the results of mixed infection of typhoid bacilli, and pyogenic and other bacteria; the pyogenic faculty of typhoid bacilli; typhoid infection of different organs without typical typhoid lesions in the intestine. Then follows a chapter on typhoid gangrene, giving its state of onset and its pathology. Chapter 4 describes typhoid affection of the joints, such as rheumatic typhoid arthritis, septic typhoid arthritis, typhoid arthritis, polyarticular and monarticular; pathologic dislocation after typhoid fever. Chapter 5 describes typhoid affections of bones. Chapter 6 speaks of typhoid abscesses. Chapter 7 is devoted to typhoid hematoma, of which only a single case is given, but an analysis was made of seventeen reported cases. Chapter 8 deals with the cerebral complications of typhoid fever, and twenty-two cases are analyzed. "It is noteworthy," say the authors, "that a bacteriologic examination was made in fifteen of the cases of meningitis, and without exception the bacillus of Eberth was found in pure culture in twelve." In 2.87 the bacillus of Eberth was found. Chapter 9 analyzes thirty-one cases of otitis media in typhoid fever. Chapter 10 refers to fifty cases of typhoid parotitis, tabulated by Dr. Westcott, and 375 cases in the Toner Lecture of Keen. Chapter 11 refers to typhoid affections of the thyroid gland. Chapter 12, of the larynx, and in the latter it may be stated that necrosis of the cartilages is a most common and most dangerous form of laryngeal infection from this cause. Chapter 13 speaks of typhoid affections of the pleura, lungs and heart. Chapter 14, typhoid affections of the esophagus and stomach. Chapter 15 is devoted to intestinal perforation in typhoid fever. Chapter 16 takes up typhoid affections of the liver and gall bladder. Chapter 17, of the

spleen. Chapter 18 of the male and female sexual organs. Chapter 19 is devoted to a discussion of specific mixed infections, such as tetanus, erysipelas, anthrax, malignant edema. Chapter 20, by George E. de Schweinitz, is on the ocular complications of typhoid fever. Chapter 21 gives the conclusions.

For the appendix to the work we are indebted to Dr. Keen and the Smithsonian Institute for the reprint of his Toner Lecture on "The Surgical Complications and Sequels of the Continued Fevers," delivered in 1876, which lecture had a more limited circulation than it is likely to attain as an appendix to this volume. We congratulate the authors on this valuable addition to American medical literature.

Diseases of Women. A Clinical Guide to their Diagnosis and Treatment. By GEORGE ERNEST HERMAN, M.B., London, F.R.C.S. With 252 Illustrations. New York: Wm. Wood & Co. 1898. Pp. 886. Price, extra muslin, \$5 net; leather, \$5.75.

If every one who wrote a book were as careful that clinical experience should precede the writing of it as Dr. Herman has been, our medical literature would largely gain in usefulness and authority. This excellent work has seven introductory chapters on general topics, such as neurasthenia, hysteria, headaches, pain in the back, chronic abdominal pain and methods of investigation. Part II discusses chronic pelvic pain, such as chronic ovarian pain, chronic uterine pains, subinvolution and chronic metritis, uterine displacements, prolapse, retroflexion, etc. Part III discusses pelvic inflammations, namely, acute general peritonitis, perimetritis, serous perimetritis, perimetric abscess, salpingo-oovitis and parametritis. Part IV is given to internal hemorrhage, as internal hemorrhages, pelvic hematocoele; Part V, general considerations of uterine hemorrhage, hemorrhages without pregnancy or new growth, hemorrhages with round tumor in the vagina, hemorrhage connected with early pregnancy, adenoma of the uterine body, cancer of the cervix, malignant disease of the uterine body, bleeding fibroids; Part VI, general considerations as to leucorrhea, leucorrhea in children, in virgins, in married women, in old women; Part VII, disorders of the vulva, pruritus, inflammation and ulceration, swellings; Part VIII, disorders of menstruation, menstruation; dysmenorrhea, obstructive, membranous, spasmodic and congestive; amenorrhea, retained menses, menstruation absent; Part IX, disorders of the sexual functions, sexual troubles and sterility; Part X, disorders of parts adjacent to the sexual organs, too frequent micturition, painful micturition, retention of urine, incontinence of urine, painful defecation, and incontinence of feces; Part XI, abdominal tumors, ovarian tumors, clinical history of ovarian tumors, diagnosis of ovarian tumors, ovariectomy, after-risks of ovariectomy, solid abdominal tumors, treatment of subperitoneal fibroids, ectopic and complicated pregnancy, inguinal hernias.

It will be seen that the scope of the work is extensive, and that the subject-matter is fairly well covered. It is no disparagement to the many excellent works on the market, to say that this book of Dr. Herman will occupy front rank among them.

Mammalian Anatomy; A Preparation for Human and Comparative Anatomy. By HORACE JAYNE, M.D., Ph.D. Part I. The Skeleton of the Cat, its Muscular Attachments, Growth and Variations Compared with the Skeleton of Man; With Over Five Hundred Original Illustrations and Many Tables. Philadelphia: J. B. Lippincott Co. 1898. Pages 816.

This work belongs to a class of which we have had too few in America, and the manner in which the publishers have brought out this beautiful volume can not be too highly praised. The type is large and clear; the paper is of the best, and the illustrations are in the highest style of the art. This treatise, of which this is the first part, is a monograph on a typical mammal, and is employed as an introduction to general comparative anatomy. The cat has been selected as furnishing a structure of the inferior animals which in certain anatomic respects approaches more nearly to man than a dog, and

is not specialized for any one mode of life, is of convenient size and easily obtained.

The introductory chapter treats of the structure and classification of bones, features, practical methods of study, with an explanation of the general terms used in the description. This introduction is then followed by a systematic study of every bone and the regions which they form when articulated. The description of a bone includes an explanation of its name, the areas for muscular attachment, its articulations, rules for rapid identification, the centers of ossification from which it is developed, its growth and its variations. The corresponding bone in the human skeleton is then carefully compared with it.

Although this volume is complete in itself, yet we shall look with interest and some impatience for the second one.

Proceedings of the American Medico-Psychological Association. Paper. Illustrated. Pp. 380. Published by the Association, 1897.

This volume has to do with the fifty-third annual meeting held in Baltimore, May 11-14, 1897. The papers included are: "Improvements of the Medical Service of Prisons, Reformatories and Penitentiaries;" "A Sketch of Psychiatry in the Southern States;" "Advances in Neurology and their Relation to Psychiatry;" "General Questions of Auto infection;" "Clinical Aspects of Auto-intoxication;" "Demonstration of Various Types of Changes in the Giant Cells of the Paracentral Lobule;" "The Development of the Higher Brain Centers;" "The Genesis of a Delusion;" "The Psychology of Insane Delusions;" "Preliminary Report, Clinical and Pathologic, of a Case of Progressive Dementia;" "Some Observations on the Use of Hyoscin;" "Aphasia, with Report of a Case;" "Hospital Records;" "The Medical and Material Aspects of Industrial Employment for the Insane;" "Insanity Following Surgical Operations;" "The Commitment and Detention of the Insane with Especial Reference to the Laws of Maryland;" "Kata-tonia;" "The After-care of the Insane;" "Training Schools for Nurses in Hospitals for the Insane;" "Myxedema-like Conditions in the Negro;" "The Constructive Forces;" "The Practical Lines of Work Needed for the Advance of Psychiatry." A number of full-page plates in colors add much to the perspicuity of the volume.

Studies From the Department of Pathology of the College of Physicians and Surgeons, Columbia University, New York. Vol. v, part I. Paper. Illustrated.

This volume comprises reprints of studies made during the collegiate year 1896-97. The studies included are: "Milk as an Agency in the Conveyance of Disease; and Low Temperature Pasteurization of Milk at About 68 C.;" "A Machine for Tubing Bacterial Media;" "A Contribution to the Study of Acute Ascending (Landry's) Paralysis;" "A Further Study of the Biology of the Gonococcus (Neisser) with Contributions to the Technique;" "Bacterial and Allied Tests as Applied to the Clinical Diagnosis of Typhoid Fever;" "Dangers of the Domestic Uses, Other than Drinking, of Contaminated Water, with Special reference to Milk and Oysters as Carriers of Bacteria;" "Report on two Cases of Tumor of the Spinal Cord, Unaccompanied by Severe Pain;" "The Lymphatic Constitution, and its Relation to Some Forms of Sudden Death;" "Notes on Polychromatic Photomicrography, with Plate in Color."

Transactions of the Medical Society of the District of Columbia, Vol I, 1897. Paper, pp. 243.

This volume covers the period from March, 1896, to January, 1897, and is edited by Drs. W. W. Johnston, G. M. Kober and J. D. Morgan. Sixty-eight papers, the most of them with discussions, and "Arguments Against Bill to Prevent Vivisection," the bill regulating testimony of physicians in courts of the District of Columbia, also the bill regulating expert evidence in courts of the District of Columbia, and the Medical Practice Act are included, with the minutes of the various sessions of the society during the period named.

MISCELLANY.

The Sins of the Pessary.—F. L. Neugebauer has collected 364 cases of injuries from pessaries, and states that in 112 there was perforation of a neighboring organ, the rest due to abuse, neglect, being forgotten, etc.—*Wien. klin. Woch.*, February 24.

Length of Time Carbon Dioxid Remains in the Blood After Intoxication.—Experimental research shows that forty-one minutes is the longest period, and sixteen the shortest, in which carbon dioxid can be detected in the blood of animals exposed to its toxic action.—*Deut. Med. Woch.*, February 24.

Infiltration of the Nerve Cells by Leucocytes.—In the investigation of the tissues of some old dogs it was found that the leucocytes had penetrated into the interior of the nerve cells, especially those of the ganglia of the posterior roots, producing peculiar alterations in the neuron as the leucocyte gradually invaded and destroyed the nerve cell.—*Presse Méd.*, March 2.

Effects of the X-rays on Osmosis.—In some recent experiments the ascent of the liquid was checked almost entirely by the action of the rays from the Crookes' tube. This effect on the osmosis may be the explanation of the alterations produced in the tissues by the X-ray.—*Presse Méd.*, March 2.

Study of Epilepsy.—The formation of a National association for the study of epilepsy and the care and treatment of epileptics is being advocated by William P. Spratling, superintendent of the Craig Colony, Sonoma, N. Y. The Doctor will be glad to hear from any who favor such a society or have any suggestions to offer.

New Publication.—*Medical Libraries*, Vol. 1, No. 1, February, 1898, has reached us. This publication will be issued monthly and is "devoted to the interests of medical libraries and bibliography." Dr. C. D. Spivak, Denver, is the editor, and the subscription price is 50 cents per annum.

Extra-uterine Pregnancy Lasting Twenty-three Months.—A fully developed fetus was exhibited at a recent meeting of the Brussels Anat. Path. Society, which had grown in the tube, in which also the placenta was inserted. After the rupture of the tube the fetus had passed into the abdomen where it had contracted adhesions with the intestines and peritoneum.—*Presse Méd.*, February 26.

Mycosis of the Nerve Centers.—J. Roux and Paviot describes in the *Presse Méd.* of February 23, the observation of a case resembling Landry's disease with the exception of a few particulars, but at the necropsy a parasite was found in the nerve centers of the spinal cord and medulla, resembling a streptothrix, which seemed to have affected the nerve centers mechanically by its enormous growth.

Placental Infection of Anthrax.—Rostowzew had occasion to observe three cases of pustula maligna faciei in pregnant women, in the fourth, seventh and eighth month, all fatal. The anthrax bacilli were found in the fetus, showing that there must have been placental infection, although they were much less numerous and paler in color. Under the influence of the infection the epithelial coat of the chorion villi loses its impermeability, so that the bacilli can pass directly through it, as Rostowzew also confirmed experimentally. He notes that this affection seems more fatal to pregnant women, as three similar cases in non-pregnant women terminated in recovery.—*Ztschft. f. Grb. u. Gyn.*, Vol. 37, No. 3.

An Extensive Operation to Remove an Enormous Vesical Papilloma is described in the *Ann. de la Soc. Méd.-Chir. de Liège* of January. It included the total ablation of the genital organs, male, and the total resection of the bladder and urethra, requiring symphyseotomy and a wide opening between the pubes, besides an opening in the perineum. The ureters were implanted in the rectum, with sounds removed forty-eight

hours later, but one of the ureters became partially detached from the rectal wall, causing some of the urine to trickle through the perineal wound. Except for this the patient seems quite restored and has gained in weight during the six weeks since.

Section on Materia Medica, Pharmacy and Therapeutics.—Dr. C. C. Fite, late Secretary of the Section on Materia Medica, Pharmacy and Therapeutics, has resigned. Dr. Leon L. Solomon, 323 West Walnut Street, Louisville, Ky., has been appointed Secretary of the Section.

Papers at the Association Meeting.—Gentlemen intending to contribute papers to the various Section meetings are respectfully informed that by a rule passed by the ASSOCIATION many years ago, all papers read at the meetings are considered the property of the ASSOCIATION and are to be published only in its Transactions. This, however, does not preclude the right to publish short abstracts of the papers in other journals.

Pathologic Anatomy of Hemorrhoids.—Microscopic examination of fifteen cases of hemorrhoids operated on, confirms the assumption that hemorrhoids are not simple varices, but angiomas, complicated secondarily by the venous stasis. The starting point is undoubtedly a local infection produced by intestinal microbes.—*Beiträge z. Klin. Chir.*, xxi, 1.

A Remarkable Leucocytosis in Whooping-Cough is one of the first manifestations of the disease, preceding the coughing paroxysms. Meunier found, in 102 numerations, that the average was 27,800, with a maximum of 51,250; the usual proportions between the lymphocytes and the polynuclear leucocytes reversed. He suggests that this remarkable leucocytosis may be found valuable in differentiating the affection for the prophylaxis of whooping cough in schools, hospitals, etc.—*Presse Méd.*, January 26.

Myelocytes in Pneumonia.—W. Türk has recently published the results of a systematic and comprehensive study of the blood in the course of various infective diseases, sixty cases. In regard to mononuclear neutrophile cells, myelocytes, he asserts, that they are especially typical in pneumonia. They are rare during the fever process, but increase always at the time of the crisis, frequently as much as 10 per cent. and over. He noted a new form of cell which he calls the "stimulation" form (Reizungsform), a mononuclear cell distinguished by the fact the protoplasm takes a peculiar brown color with the "triabid stain."—*Wien. klin. Woch.*, February 3.

Rigidity of Ankylosis of the Spine is an affection recently described by von Bechterew for the first time, his monograph being based on the observation of six cases; no necropsies. The anchylosing process affects the bones and later the meninges, causing compression of the roots of the spinal nerves and determining various sensory, motor and trophic disturbances. As the spine becomes rigid it assumes a posterior convex curvature, usually confined to the superior dorsal region. Three of his cases had nervous antecedents and the other three attributed the affection to traumatism. No infective disease nor intoxication could be discovered.—*Deut. Zetschrift f. Nervheil.*, xi, 3, 4.

Effect of Extreme Heat on the Nerve Cells.—Experimentation with rabbits exposed to extreme heat showed that the motor cells in the spinal cord were altered, the protoplasmic prolongations tumefied, color changed, etc., and the necropsy of two patients succumbing to tetanus and scarlet fever, whose fever had risen to 102 and 106 degrees, disclosed similar alterations. When the animals survived the heat, the cells were restored to normal in three days.—*Klin. Therap. Woch.*, January 30.

Permeability of the Eschar Produced by the Cautey.—Experiments in this line are reported from both Holland and Germany, in which the ear or peritoneal cavity was cauterized and micro-

organisms placed on the outside of the resulting scab. Ten Brink found that the staphylococcus easily penetrated the scab from the hot iron and was found in the subjacent tissues, but Cohn reports that the eschar from nitrate of silver protects the tissues beneath, and also that its bactericidal properties killed anthrax, diphtheria germs and streptococci in contact with it. The eschar resulting from the use of cuprum sulfuricum proved equally effective.—*Nederl. Tijd. v. Ges.*, January 29, and *Berl. klin. Woch.*, 1897, No. 52.

Removal of Large Exostosis During Pregnancy.—W. Kramer reports an unusual case in which a large exostosis had developed on the inside of the pubic bone, closing the canal and rendering a natural birth impossible, when the woman arrived at the hospital already in labor. Cæsarean section was successfully performed and the woman advised to return after a few weeks to have the bony growth removed. She did not appear again for a couple of years, when she was already in the sixth month of a second pregnancy. To avoid interference with the pregnancy, Kramer extirpated the tumor through the pelvic outlet, although this did not allow full inspection by the eye, and curetted the space left on the bone, 5 to 6 cm. in diameter. Dismissed perfectly recovered in a month; normal delivery in due time.—*Chl. f. Chir.*, March 5.

Europeans not Immune Against the Plague.—The death of an English nurse, Miss Morgan, at the Poona Plague Hospital, from that disease, the death of a European nurse at the Parsee Plague Infirmary, and the severe attack sustained by Dr. H. W. Bruce of Malegaum, together with a number of similar events, have shown quite conclusively that the supposed immunity of whites against the plague is not proven. As a general rule, Europeans are so placed as to be under comparatively slight dangers of infection, as compared with the poorer classes of natives, and their habits of life safeguards them from contracting, or succumbing to, the disease. When Europeans are seriously and repeatedly exposed to infection, as is the case with hospital attendants, the frequent occurrence of cases contradicts the supposed invulnerability.

Pathology of Acromegalia.—Strümpell concludes from a case he has been observing for years and from the necropsy, that acromegalia is probably an endogenic affection due to the congenital malformation of certain organs with it remains to locate. The pituitary body has been incriminated by various authors and, in fact, there is scarcely a case on record with entire absence of all tumor of the pituitary body. In the present case nothing abnormal was found outside of the simple hypertrophy of the bones, subcutaneous cellular tissue and of the skin, but a soft tumor, sarcoma, in the pituitary region, which had invaded the nasal fossæ and right orbit after destroying the sphenoid bone. He adds in conclusion that acromegalia can be considered the exact opposite of scleroderma; one, hypertrophy, the other, atrophy, resembling the antagonism noticed between Basedow's disease and myxedema.—*Deu. Zt. f. Nerv.* xi, 1, 2; *Sem. Méd.*, February 26.

Glycogenesis in Normal and Pathologic Tissues.—In a recent communication to the *Presse Méd.*, January 20, A. Braut proves that glycogenesis is a property inherent to all the cellular protoplasm at different periods of their existence, and although apparently they may have lost it, yet when incited to a more active nutrition they regain this property of elaborating and storing glycogen. The animal cell, he asserts, manufactures glycogen directly, as the vegetable cell manufactures starch, with the difference that it is not indiscriminately produced; it always corresponds to certain distinct nutritive processes. He shows that Claude Bernard was mistaken in assuming the liver to be the sole glycogenetic organ, as he has established that glycogen is found normally in the muscles and cartilages as well as in the liver; it is absent from almost all the other organs. It is, therefore, reasonable to

suppose that it is especially valuable to the liver and muscles, and he considers that the glycogen found stored in the cells is designed for an alimentary reserve, a local provision to be utilized on the spot. His important conclusions in regard to glycogenesis in neoplasms as an indication of their rate of development have already been noted in the *JOURNAL* (Vol. xxviii, page 1093).

Work of the Muscles in the Pneumatic Cabinet.—G. v. Liebig describes some tests on different persons in which the number of times a given weight could be lifted with the outstretched arm, in pneumatic cabinet (at a pressure of two atmospheres), and also outside, were compared. The tests showed that the muscles could accomplish nearly 50 per cent. more work with the double supply of oxygen, which confirms the experience that miners can do work in the compressed air of the iron mines much beyond their strength outside, and with less subsequent fatigue. A. Mosso believes that the extra supply of oxygen affects the brain also, rendering it less susceptible to the sensation of fatigue. In some lifting tests with the middle finger when the muscles refused to act, he continued the exercise by electric stimulation of the nerves involved, and in a few minutes found that he could continue the exercise without the electric stimulation, which he thinks indicates that it was the brain, the will, that became fatigued, rather than the muscles.—*Deu. Med. Woch.*, March 3.

Pathogenesis of Affections of the Articulations.—The synovial membrane not only differs from other serous membranes by the lack of endothelium, but by a peculiarly rich and elbow-shaped vascularization, according to a recent study by Hofbauer. The capillaries are extremely numerous and penetrate close to the surface, under which they bend and extend in a tortuous course parallel and very close to the outer surface. This arrangement of the capillaries explains the tendency of the articulations to be early involved in the course of any infection of the blood, owing to the great afflux of blood and of the contained irritant substances, leading to accumulations of the microbes or toxins in the synovia and joint. The extremely thin partition is soon traversed by chemicals or microbes, in the same way as they pass into the urine through the glomeruli, although less easily. The contaminated fluid has then no outlet and everything favors the development of the germs, as absorption from the articulations is extremely slow.—*Wien. klin. Woch.*, January 27.

Anytin, the new substance that renders insoluble substances soluble, is obtained from a hydrocarbon containing 10 per cent. sulphur treated with sulphuric acid, then neutralized with ammonia and precipitated with alcohol, which removes all the insoluble elements. The brown sulpho-ammoniacal salt thus obtained (with the addition of 33 per cent. water) has been named anytin by Helmers, its discoverer, and has the property of rendering otherwise insoluble substances in combination with it easily soluble in water. The anytols, as these combinations are called, have been studied by Loeffler during the past year, especially the aromatic group, phenols, cresols, etheral oils, camphore and iodine, although his most comprehensive investigations were with m-cresol-anytol and iodine-anytol. In respect to diphtheria and anthrax bacilli and streptococci, anytin alone is as strongly bactericidal as ichthyol and in about the same degree, but does not affect other germs any more than ichthyol, but the meta-cresol anytol (40 per cent. m-cresol to 60 per cent. anytin) destroys all pathogenic germs with equal effectiveness. It has also the peculiar property of preventing the coagulation of albumin at a boiling temperature by the addition of even 4 per cent. A 1 per cent. solution of m-cresol-anytol has the same bactericidal power as a 3 per cent. carbolic solution, while the 3 per cent. solution is much more powerful, killing all cultures almost totally in less than a minute. Virulent anthrax spores were killed in a 5 per

cent. m-cresol-anytol solution in thirty-six hours, which suggests its application to the disinfection of catgut, as it does not injure the catgut to remain in it for forty-eight hours although eight days is destructive. A 1 per cent. solution does not affect the tissues (a 3 per cent. solution is slightly irritating) and is harmless and effective in disinfecting hands and wounds, and has been found more beneficial than any other substance in treating fifty cases of ozena with "most satisfactory results." A 3 per cent. solution was found extremely effective in arresting fresh experimental diphtheritic processes, neutralizing the toxins as well as killing the germs, which recommends it for local applications in diphtheria.—*Deu. Med. Woch.*, March 10.

Protest Against the Gallinger Bill.—To the Hon. Edward Murphy, Jr., United States Senator. *Dear Sir:*—The Academy of Medicine of Syracuse, N. Y., respectfully asks you to give serious attention to *Senate Bill 1063, Calendar No. 136*, a bill purporting to prevent further cruelty to animals in the District of Columbia. The bill is delusive. It is but an enterprising wedge, having as an ulterior object the prohibition, practically, of vivisection in the District of Columbia, and as an ultimate object the prohibition of vivisection throughout the United States. The passage of the bill is favored by many well meaning but misled people, who have been influenced by persistent misrepresentation and exaggeration on the part of certain persons whose fanaticism is aimed at the foundation of scientific progress in medicine. Only too few investigators are engaged in that practical study of physiology and pathology which demands for its profitable pursuit in interests of suffering humanity, perfect freedom in the matter of vivisection. We protest against the passage of a bill which is a part of a cunning scheme intended, first to hamper, and then to stop the most important investigation scientific medicine has ever attempted. We hold, rather, that the government should liberally encourage in every proper way the continuation of the work, impossible without vivisection, begun by such men as Pasteur in France, Lister in England, Koch in Germany, and Sternberg in the United States. (Signed by the officers and Fellows of the Academy.)

Closing Exercises of the Fourth Session United States Army Medical School.—The closing exercises of the session 1897-98 of the Army Medical School, Washington, D. C., took place in the hall of the library of the Surgeon-General's office at 3 p.m., Friday, April 1, 1898. The walls were handsomely draped with the national colors, which festooned the portraits of former Surgeons-General of the Army and other professional notabilities. Many ladies were present in the audience, which consisted mainly of medical men of the city and the national services. Fewer military men were present than on former occasions of the kind, probably on account of the intensity of the interest just then felt in the strain of our relations with Spain. Colonel Charles H. Aiden, Assistant Surgeon-General, president of the faculty of the school, opened the proceedings. In the course of his remarks he said:

"It is hardly necessary for me to tell you anything of the organization and objects of the Army Medical School, as these subjects have been fully made known in the Annual Reports of the Surgeon-General for several years past, and in articles in the medical and general press.

"When the present class leaves the School there will be twenty-four medical officers who have taken the entire course of instruction immediately after their appointment and before going out to their future stations, and about an equal number of assistant surgeons of older date, either on leave or stationed in the vicinity of Washington, have taken partial courses of instruction, chiefly in the laboratories. It will be seen, therefore, that quite a considerable number of assistant surgeons of the Army have felt the influence of the School. The beneficial effects of the course of instruction here held in promoting the efficiency of the medical department and therefore benefiting the Army at large have been noted by many officers of the line, of other departments and by friends of the Army in civil

life; and their appreciation, I am sure, must be very gratifying to the founder of the School, as it is to the corps of instructors.

"The order of daily duties at the School during the present term has been substantially the same as that in former years. The morning hours from 9 A.M. to 12 M. have been passed by the class in the Microscopic Laboratory; the hours from 1 to 3 P.M. in the Laboratory of Sanitary Chemistry, and at 3 o'clock there has been, for five days in the week, a lecture on the 'Duties of Medical Officers,' 'Military Surgery,' 'Military Medicine,' or 'Military Hygiene.' Instruction in hospital corps drill and first aid has been given at Washington barracks at 9 o'clock on Saturday mornings, and later in the morning the Class has been instructed in riding at Fort Myer, Virginia, by Lieutenant Herbert White, 6th Cavalry, through the courtesy of Colonel Sumner the commanding officer. Weekly surgical clinics have been held at the Barnes' Hospital by the Professor of Military Surgery, and instruction in optometry has been given by Captain De Shon, one of the Staff of the School, aided by clinical instruction by Dr. W. N. Suter at the Episcopal Eye Hospital, and also by Dr. L. H. French. Several other auxiliary courses of lectures have been delivered as in former years; one on 'Military Law,' by Lieutenant Colonel Davis, of the Judge Advocate General's Department, Professor of Military Law at West Point, N. Y.; a clinical course on 'Mental Diseases' at the Government Hospital for the Insane, by Dr. George W. Foster through the courtesy of Dr. W. W. Godding, the Superintendent; on the 'Army Medical Library' by Dr. Robert Fletcher, F.R.C.S., and on 'Parasites in Man' by Prof. C. W. Stiles, Ph.D., Department of Agriculture. Two new features of the present course should be noted: one, that the session was extended from March 1 to April 1, to give more time for the completion of the course of instruction; the other, the foundation of the Hoff Memorial Prize Medal. This subject will be explained and the medal awarded by Surgeon-General Sternberg later in the exercises.

"Gentlemen of the Class of 1898: Upon the close of the present exercises you are relieved from further attendance upon the duties of the School, and become subject to the operation of the orders of the War Department assigning you to your future stations. In passing out from this institution you have the warmest wishes of your instructors for your future success and welfare. We feel confident that you will acquit yourselves as officers and gentlemen and efficient surgeons, and that you will do credit to the School, to your Corps, to the Profession and to the Army."

Colonel Alden then introduced Prof. P. S. Conner of Cincinnati, Ohio, who, as a member of the Army Medical Department, had rendered meritorious services during the war of the rebellion, and who has never ceased to maintain his interest in military surgery and in the Medical Department of the Army.

Professor Conner, in his address, reviewed the history of the Medical Corps of the Army from the early times when its members spent their lives on the advance line of our western civilization to the present, when the isolation of the Army surgeon has come to an end, along with the conditions that necessitated the establishment and maintenance of military posts in the wilderness. He reviewed the work of Allison, who as post surgeon of Fort Washington, Ohio, was Cincinnati's first physician. He spoke of the advances made by the early medical officers in our knowledge of the topography, climatology, ethnology, geology, zoology and botany of the country, and reviewed the contributions of the members of the Corps to the literatures of medicine and surgery, mentioning with eulogy many names that are familiar not only in the Army but to the profession at large; and he made honorable mention of many who, like himself, went out into civil life carrying with them those principles of honor and integrity and devotion to duty which are the very life and soul of an Army officer. He congratulated the class on the completion of its academic labors, and testified to his appreciation of the advantages provided for the younger members of the Corps by the establishment of the special courses of the School, which he regarded as one of the best works done by the Surgeon-General of the Army. In concluding he urged the graduates to keep in touch with the general and local profession, taking their places as members of the greater and higher medical Corps which embraces all the good men and true who are advancing medicine and benefiting mankind.

The certificates of attendance were then presented by Surgeon-General Sternberg to the members of the class in the order determined by the results of the examinations held at the close of the term, as follows: 1st, Lieut. Brainard S. Higley, Jr.; 2d, Lieut. Henry Page; 3d, Lieut. Jere B. Clayton; 4th, Lieut. Bailey K. Ashford; 5th, Lieut. Henry A. Webber; and 6th, Lieut. George Rauchfuss.

Dr. Higley is to be congratulated on his success. At the competitive examination held in October last for entrance into the service he was fifth on the list of six accepted candidates; but his earnest work during the session has made him the first recipient of the Hoff Memorial Medal founded recently by Major J. Van R. Hoff, Surgeon United States Army in memory of his father, a surgeon of United States Volunteers during the war, and afterward a member of the regular medical corps, to be awarded annually to the student officer who attains the highest general average at the School.

After some appropriate remarks by the Surgeon-General the members of the class were introduced to Professor Conner, and the exercises ended with an inspection of the museum, library and laboratories.

Louisville.

HEALTH.—The following ordinances, suggested by Health Officer Allen, have been adopted by the Common Council: An ordinance regulating sanitary affairs in manufacturing establishments, lodging houses, boarding houses, etc. The first paragraph of the ordinance is designed to prevent the crowding of persons into one or more rooms; the second paragraph provides that these buildings be adequately provided with ventilation and closets. An ordinance requiring birth certificates to be returned to the health office by accoucheurs, physicians and midwives, with a penalty of from \$5 to \$20. An ordinance requiring clergymen, magistrates and all having right to perform marriages to report all marriages to the health office. This includes a penalty as the previous one.

Philadelphia.

A PAY HOSPITAL for contagious diseases to be erected in Philadelphia. A company has been formed in the city of Philadelphia for the purpose of building a hospital for the treatment of contagious diseases. The company is now endeavoring to raise \$100,000 to be expended for the grounds and building. One new feature of the proposed hospital is that all patients must pay according to their means, and may be attended by their own private physicians. Should success crown the efforts of the incorporators it will necessarily be a boon to those afflicted with any disease of a contagious nature, besides affording the greatest relief and, too often, inconveniences in treating these cases at their homes. The officers are: W. M. Ashman, president; Justus C. Strawbridge, secretary; Clara T. Dercum, treasurer. Among other directors may be mentioned Drs. George M. Gould, J. Madison Taylor, Frederick P. Henry, Edwin E. Graham and Edwin Rosenthal.

MEETING OF THE PENNSYLVANIA HEALTH AUTHORITIES AND THE STATE MEDICAL SOCIETY.—The fifth annual meeting of the Associated Health Authorities of Pennsylvania will be held at Lancaster, Pa., May 18 and 19. At this meeting "Educational Hygiene" will be the principal topic of discussion. By invitation of the State Board of Health, the Associated Health Authorities and the State Medical Society will, on May 20, pay a visit to the Marietta vaccine farms. It is expected that Governor Hastings will be present at the opening ceremonies.

SEPTICEMIA FOLLOWING A CHILD'S BITE.—While doing an intubation upon a child suffering from membranous croup, Dr. Dowling W. Benjamin of Camden, N. J., was unfortunate in having his finger caught by the child's teeth, causing a severe lacerated wound from which septicemia followed. An operation was very promptly done and the wound thoroughly cauterized. At last accounts the Doctor was resting easy.

Detroit.

WAYNE COUNTY MEDICAL SOCIETY—At the regular meeting of this society, held March 31, Dr. W. Warren read a paper entitled "Tracheitis and Chronic Bronchitis." The Doctor explained how a pharyngeal inflammation can pass downward into the trachea without affecting the vocal chords or the structures immediately adjacent. This, he said, is because of certain histological conditions present in the larynx, viz., that portion of the larynx near the true vocal bands is more dense in structure, the glands are diminutive in size and number, the blood vessels are smaller and less numerous and the mucous membrane is in close apposition with the perichondrial wall; it is for this reason less susceptible to attacks of inflammation than the loose mucous membrane that extends above and below it. The author gave as factors influencing the character and severity of bronchitis, age, city life and humid and severe climates. In discussing the diagnosis, he dwelt particularly on the difference between this disease and pulmonary tuberculosis, the chief points being the presence or absence of Koch's bacillus in the sputum, early or late emaciation the condition of the skin, and the age. The treatment he divided into climatic and medicinal; the latter into general and local. The climate best adapted to these patients is one characterized by mildness, equability and comparative dryness with moderate elevation above the sea level, such regions being found in the mountainous parts of Tennessee, the Carolinas, in the Gulf region and the table lands of the Southwest. In regard to the prophylaxis the Doctor said that persons with any tendency to the bronchial habit should be carefully instructed regarding the matter of clothing and bathing: that treacherous contrivance known as the "chest protector" ought to be discarded and patients should be taught that a well-groomed skin is of more value than any artificial contrivance. By cold sponging and friction of the neck, chest and back one can so temper the skin as to become more or less indifferent to the character of the wind. In the matter of internal medication we must seek to modify the bronchial mucous membrane so as to alter the secretion and combat the congestion; expectoration must be facilitated: the cough must be allayed, and the general health be improved. Among remedies mentioned were the balsamic preparations and liquid extract of hydrastis Canadensis, this last being found of much value given in doses of 20 to 30 drops four times daily. For local treatment the author recommended the intralaryngeal injections of a solution of alumnol and preparations of oleum petrolati with menthol, eucalyptol and essential oils. These are introduced by means of the laryngeal syringe, a sample of which he exhibited to the society. Dr. I. L. Polozker followed with a paper on "The Treatment of Vaginitis in Children." The author stated that in his experience 70 per cent. of the cases of vaginitis in young girls was due to the specific germ of gonorrhea. The essential features of the Doctor's paper were the poor results and disagreeable effects attending the use of such preparations as permanganate of potassium and silver nitrate, and the recommendation to the profession of the employment of a solution (1-500) of formaldehyde locally, containing glycerin to prevent irritation after its use.

HEALTH REPORT for the week ending April 1 is as follows: Total number of cases of diphtheria remaining, 7, 1 death having resulted from the disease: scarlet fever, 15, no deaths; number of births, male, 40; female, 34; deaths, 85; under 5 years 32.

Hospitals.

THE FRAMINGHAM HOSPITAL, by the will of the late Mrs. Caroline McKinstry, South Framingham, Mass., receives \$5000.—A recluse, William J. Hoadam, who recently died in Philadelphia of nephritis, and who had lived in great simplicity at the foot of an alley, left his fortune of \$50,000 to the Pennsylvania Hospital.—Charlotte Quincy of Beverly, N. J., recently bequeathed \$500 to the children's ward of the Pennsylvania Hospital.—The will of the late Amos R. Eno, for many years the owner of the Fifth Avenue Hotel, provides that the Demilt Dispensary and the New York Cancer Hospital shall receive \$5000 each. The Society for the Relief of the Ruptured and Crippled and five other charitable organizations receive a like amount.

Colleges.

THE GRADUATING CLASS at the Michigan College of Medicine, Detroit, numbered eighteen.—The nineteenth annual commencement of Central College of Physicians and Surgeons, Indianapolis, was held March 23. There were thirty-five in the graduating class.—From the Medical Department of Iowa State University, March 30, were graduated fifty-four young doctors.—Beaumont Medical College, St. Louis, granted twenty-eight degrees at the annual commencement, March 25.—The graduating class of the Wisconsin College of Physicians and Surgeons, Milwaukee, numbered twenty-two at the annual commencement held March 29.—The fortieth annual commencement of Atlanta (Ga.) Medical College was held March 28, with a class of forty-six graduates.—The Southern Medical College, Atlanta, Ga., held its nineteenth annual commencement March 30, with twenty-eight graduates.—There were seventy-three graduated from the Louisville Medical College, March 25.—The graduating class of the Medical College of Indiana, Indianapolis, numbered seventy-five.—Vanderbilt University, Nashville, Tenn., awarded the degree of M.D. to sixty-six on March 30.

Societies.

The following meetings are noted:

Illinois.—Chicago Medical Society, April 6; East St. Louis Medical Society, March 21.

Iowa.—Northwestern Iowa Medical Association, Ida Grove, March 22.

Michigan.—Saginaw County Medical Society, Saginaw, March 28.

Minnesota.—Ramsey County Medical Society, St. Paul, March 28.

Missouri.—St. Louis Medical Society of Missouri, April 2.

Ohio.—North Central Ohio Medical Society, Mansfield.

Wisconsin.—Central Wisconsin Medical Society, Madison, March 29.

CHANGE OF ADDRESS.

Arthur, H. M., from Indianapolis to Glen Dale, Ind.
Beaudoux, H. A., from Winona, Minn., to Fargo, N. D.
Campbell, C. E., from Columbus to Grafton, Ohio.
Clement, W. R., from Paducah to Princeton, Ky.
Cohoe, W. H., from Indianapolis to Burnsville, Ind.
Engle, H. P., from Iowa City to Newton, Iowa.
Fleemer, O. F., from Indianapolis to Knightstown, Ind.
Hakanson, A., from 7746 Coles Ave. to 153 92d St., Chicago, Ill.
Harvey, D. M., from 911 Laguna St. to 419 3d St., San Francisco, Cal.
Kilgore, F., from Indianapolis to Yorktown, Ind.
Kercher, J., from 104 E. 18th St. to 117 Sedgwick St., Chicago, Ill.
Lawrence, F. F., from 103 N. Fourth St. to 328 E. State St., Columbus, Ohio.
Maxwell, C. L., from Hardy to Forestburg, Texas.
McCall, N. J., from Indianapolis, Ind., to Elkton, Mich.
Petzke, E. A., from Racine, Wis., to Evanston, Ill.
Runkel, A. E., from Milwaukee to Jefferson, Wis.
Roler, A. H., from 2843 to 2380 Indiana Ave., Chicago, Ill.
Thomason, H. D., from Albion, Mich., to Missoula, Mont.
Walker, F. E., from Iowa City to Ladora, Iowa.

LETTERS RECEIVED.

Ashmead, A. J., New York, N. Y.; Arnold, Philip, Elizabeth, Ill.
Bridges, J. R., Kahoka, Mo.; Brennecke, Herman A., Aurora, Ill.; Bowerman, W. G., Cohoctah, Mich.; Brown, Mark A., Cincinnati, Ohio.
Cokenower, J. W., Des Moines, Iowa.
Eldridge, E. F., Grand Junction, Colo.; Eby, H. W., Elida, Ohio; Egbert, Seneca, Philadelphia, Pa.
Furay, C. E., South Omaha, Neb.
Graham, J. W., Denver, Colo.
Hay, E. C., Hot Springs, Ark.; Haggard, W. D., Jr., Nashville, Tenn.
Kelso, J., Woodland, Pa.
Laplace, Ernest, Philadelphia, Pa.; Lyons, J. B., Charlestown, Mass.
McFarland, D. W., Stamford, Conn.
Presbyter Hospital of the City of Chicago, Chicago, Ill.; Procter & Collier Co., The Cincinnati, Ohio.
Root, E. H., Chicago, Ill.; Rixford, Emmet, San Francisco, Cal.; Rawlins, John A., Galeua, Ill.; Reagan, C. G., Du Quoin, Ill.
Sulter, A. Walter, Harkimer, N. Y.; Saunders, W. B., Philadelphia, Pa.; Smart, Charles, Washington, D. C.
Welch, William H., Baltimore, Md.; Wingate, U. O. B., Milwaukee, Wis.; Waxham, F. E., Denver, Colo.; Weirick, C. A., Chicago, Ill.; Wellner, H., Concord, N. H.

THE PUBLIC SERVICES.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from March 26 to April 1, 1898.

Major Charles K. Winne, Surgeon, leave of absence granted on surgeon's certificate of disability is further extended six months on surgeon's certificate of disability.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending March 26, 1898.

Surgeon L. G. Heneberger, detached from the "Maine" and ordered home to wait orders.

Surgeon S. H. Griffith, detached from the museum of hygiene, Washington, and ordered to the "Mayflower."

ANATOMIC RESEARCHES ON YELLOW FEVER.

BY EDWIN KLEBS, M.D.

PROFESSOR OF PATHOLOGY RUSH MEDICAL COLLEGE AND POST-GRADUATE
MEDICAL SCHOOL.

CHICAGO, ILL.

Yellow fever, a true American disease, originating in the West Indies, is a permanent menace to the United States. So long as unhygienic conditions persist in Cuba, supported by a state of, it seems, permanent revolution and destruction, the southern parts of this land will never enjoy the security so necessary for the development of a general happy state of the population. But it may be asked, Is the terror excited by such invasions and the rigorous quarantine executed in consequence of this feeling of the population really necessary? We have learned in the last years by a more intimate knowledge of the causes and the manner of infection, that the severest diseases lose most of their danger and cease to excite the population. Relying on the possibility of securing himself against the infection, man will no more relinquish his home in blind terror. I might refer to the "Go-not-away-Club" of Mobile and possibly other localities in the infected parts of the South as a commencement of a deeper and more sure insight into the nature of this disease and infectious diseases in general.

Indeed modern bacteriologic science has shown us that very few infectious diseases are disseminated through the air. The big fires burning in the streets for the purpose of cleaning the air in times of bubonic pest, are seen no more. Only the quarantines remember this old idea that the person of man is the conveyor of the disease and must, as such, be retained under observation as long as the disease is not broken out.

The more cruel house quarantine, surrounding an infected inhabitant, which prohibits every movement of the persons included, together with the general quarantine, the so-called shot-gun quarantine, has been in general use, in the broadest way, in the last epidemic of yellow fever in the Southern States of the Union; the first exposing the sound members of a household to the infection; the second compelling the well-to-do people to leave the country before they should become prisoners in their own homes.

Science has corroborated the old, popular conviction that the body of the sick contains the germs of the disease and can spread them in different manners, depending upon the parts in which the germs are developing and from the biologic conditions of these germs. No better opportunity for dispersion of germs can be found than in diphtheria, where the bacilli are developing on the surface of the mucous membranes of the mouth, the pharynx or the nose and throat.

Doubtless these germs will be spread around the diseased person by cough and expectoration, but we do not on this account confine the whole family. We have done enough if we seclude the patient in a well aired room and with disinfectants destroy the germs in the immediate surroundings, and prohibit contact with him by other persons except well trained nurses. No other means are needed in typhoid fever and Asiatic cholera.

As to the general quarantine, used for the seclusion of towns and lands, its insufficient character is shown by so many experiences, that no modern hygienist will now advise it. That this measure is only efficient in a few instances in which a despotic ruler secludes himself and his court by closely posted soldiers, is shown by the experience of Zarskoje-Selo at the time cholera spread over the world in spite of all quarantines on the frontiers of the different states. Instead of this insufficient quarantine, in the last epidemic of cholera in this decade, the European governments, Germany first, organized a system of medical observation in all directions in which the floating population moved, in the streets, the railroads and the rivers, one observation line following the other at due distance. The infected persons could be detected and retained in a much surer way than by the old fixed quarantine. This same system was executed with full effect in our land when smallpox invaded the South. Why should it not be in a yellow fever epidemic? The answer lies in the blind terror, provoked by this disease, only sustained by our ignorance of the natural manner of the dissemination of this disease. So every addition to our knowledge on the nature of the disease must help to abolish a very natural, but also very dangerous feeling.

To understand the manner of dissemination of yellow fever we must bear in mind the following facts:

1. The disease is transported by sick people, not by goods and not by water. The two latter are absolutely excluded, as no case is known in which it was imported by the products of West India, Central or South America. It is introduced largely in the warmer regions of North America, Africa and Europe. The epidemics in 1817 (Spain, Livourne), must have originated by lingering diseases on board the ships. Without this suggestion it can not be understood why the same accident did not occur in our times with a much greater commerce. The few cases that arrive in Europe are promptly caught in the landing harbor; the goods are not infectious.

That water does not act as a propagator of the disease is shown by the fact that an epidemic never follows a river downward, but spreads upward, as in the Mississippi Valley. In smaller towns, as in Mobile, Ala., different centers of infection are formed, in which are found the first cases imported. That was demonstrated to me by Dr. Hermann Mohr, who visited with

me all parts of Mobile in which cases of yellow fever had occurred.

2. The personal contagion is not direct or confined only to a very near contact. In many cases of supposed direct contagion the infection was taken up before and in another manner. The best proof for this opinion is given in the recent publication of Dr. Hamilton R. Jones of the Isolation Hospital in New Orleans (*JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*, 1898, No. 9). He writes: "No case of yellow fever was traced to the Hospital in spite of the fact that three of the Sisters had not had it. The ambulance superintendent had never had it, and was frequently covered with black vomit. Fourteen cases passed through the wards, who did not have the disease, none of whom contracted it, and of the army of pioneers engaged in destroying the infected buildings and in general cleaning up, numbering in all considerably over a hundred persons, not one contracted the disease."

Certainly, the greatest antiseptic precautions were taken in the Hospital, but the contagion by the air, this bugbear of yellow fever, favored also by physicians, would not have been excluded by such means.

3. The contagion, emanating from an individual, must be deposited in his surroundings before it can infect other individuals. That this is so is shown by a yellow fever case originating in Whistler (near Mobile), in December, 1897, long after the epidemic in Mobile was extinguished. A workman of the railroad moved to a house in which there had been cases months before, and which had been cleaned and disinfected; there he was infected and died suddenly.

4. The yellow fever often develops very slowly in certain places; the nature of the disease is only detected later, when graver cases follow the lighter ones. So in Ocean Springs, where the first cases were considered as dengue.

The State Board of Health of Mississippi declared that the first case was yellow fever imported from Guatemala in March. The same statement was made in Mobile.

The older observers, as Gérardin of New Orleans (1817), speak of endemic and epidemic forms of yellow fever. The first form was at this time present in New Orleans, as it is now present in Havana, and many places in Central America and Brazil. Near Bahia, therefore, the German-Lloyd steamship line has a station for its sailors, to which they are removed immediately after arrival.

We must conclude from all this, that the disinfection of the sick and their surroundings is fully sufficient to destroy the germs and check the disease.

We come now to the second part of our subject; the germs of yellow fever.

G. M. Sternberg has made a very careful examination of the question and has shown that all the bacteria which he and others before him had found, seemed not to be the true causes of the disease. Only when Sanarelli published his researches did he doubt, and think that his X-bacillus was probably identical with the bacterium discovered by Sanarelli, inclined to this opinion, it seems, by the apparent results of inoculations made by the Italian author. But in carefully studying the various publications of Sanarelli, I could not suppress some doubts. If the relatively large and slightly stainable bacillus, known as Sanarelli's bacillus icteroides, was the true cause of yellow fever it would be curious if it had not been detected before. Years ago I had examined preparations received from

Rio de Janeiro and could not detect any bacillus in the fatty degenerated liver. Sanarelli could not find his bacillus in every case, which seems strange, if the bacillus is so easily stained and cultivated. Further, Sanarelli's is a pronounced water bacillus, and I must accentuate that yellow fever is not conveyed by drinking water. If I had not in younger years fallen into possibly the same error, I would not venture an opposition, the more as I am not quite sure whether Sanarelli has infected men with his bacillus or only with the toxins prepared from his cultures. I hope the last, for the first experiment would seem to be unjustifiable, the more as it would be futile, if executed in a place in which yellow fever was present. As this may be, I will tell my own error. As I worked, more than twenty years ago in Italy, with Tommasi-Crudeli on the causes of malaria, we found a bacillus in the malarial earth which cultivated and injected into rabbits, gave intermittent fever with enormous swelling of the spleen. We were very sure that we had found the true cause of this disease, for, what better proof could be thought of than the reproduction or synthesis of such a characteristic disease as malaria? But we were very soon undeceived by Marchiafava, who as assistant of my friend, had followed our researches. He found the plasmodium in the blood, and it was sustained by that glorious anatomic discovery the older, but at this time slighted observation of Laveran.

Naturally, in our cultures we had, besides our bacillus, the malaria protozoa, that is as yet not known or ever detected outside of the body. Could not the same error occur in the experiments of Sanarelli, as yellow fever is by no means as typical an affection as malaria?

How can we go out of this trap that nature has placed in the way of truth-searching pathologists? Only by anatomic research, which has built up our science, and will accomplish it if perfection is at all attainable; what we can observe with our eyes can not be delusion.

Among the organisms vegetating in higher animals the protozoa or protists seem to play a foremost rôle. They have the property to act as cell parasites. I have shown, as the young assistant of Virchow, that the psorospermia, developing in the epithelial cells of the intestines and the gall ducts of rabbits (seen first by Remak), were living bodies, not eggs of worms, and that they promote, after having penetrated into the epithelial cell, a progressive hypertrophy of these elements. The two constitute a sort of partnership. Much later the plasmodium malariae, living in the interior of red blood corpuscles, was detected. A third form are the amebæ in dysentery and tropic liver-abscess, on which Kartulis in Cairo (Egypt), and Councilman in Boston, Mass., have done excellent work. These are not intracellular, but appear as the psorospermia (or coccidia) in the passage from the intestine to the liver, a fact that will also be of high value in the study of yellow fever.

As I commenced to study yellow fever preparations, received from Dr. Hermann Mohr in Mobile, Ala. (from two cases, preserved in alcohol: stomach, duodenum, pancreas, spleen, liver, kidney and heart), I thought to try the different anilin dyes in combinations, hoping that if the organs contained foreign organisms these, like the body cells, would have a different power of election for one of these stains.

I was not deceived. First, using mixtures of methylen blue and saffranin, I found a very surprising pic-

ture in the liver of yellow fever. But the best results were given by a mixture of seven parts of my parafuchsin kresol solution for tubercle bacilli, mixed with three parts of methylen blue (concentrated solution in borax 5 per cent.), and three parts methylen green, 1 per cent. This mixture, which is somewhat thick, can be used full strength or diluted with equal parts of distilled water. If diluted, the staining must be prolonged. The decoloration and differentiation must be made very carefully, if alcohol is used; the blue color of the slice, which should not be thicker than 1/100 millimeter, must never be eliminated. The use of anilin oil and xylol (Weigert) is far better for the decoloration.

If this method is applied correctly, the preparations of the liver give a very surprising picture. Between the lines of the bluish tinged liver cells one remarks intensely stained red masses, oftentimes forming stripes and masses larger than the liver cells. The last are transformed and nearly destroyed by fatty degeneration in the median parts of the acini, and compressed by the red masses, whereas in the center and peripheral parts only isolated red spots are disposed between the liver cells. The red masses consist of round or oval-shaped, or irregular balls which will not conglomerate.

With higher powers, one remarks two constituents of these red masses, very deep stained round, oval or egg-shaped bodies, and slightly stained masses, surrounding the first. Oftentimes in one red mass are included two or more of these bodies, somewhat larger than a human red blood corpuscle, but oval-shaped and of quite homogeneous structure. It is not difficult to demonstrate that the greater, slightly reddened masses are no other than very enlarged and, in their coloring qualities, deeply changed leucocytes. Oftentimes they contain the blue stained nucleus, somewhat altered, elongated or otherwise deformed. We can seldom detect well conserved leucocytes, which contain the red body included in the blue stained protoplasm. But not all of these red bodies are included in cells. We also find them free between the liver cells, and observe here the largest forms, which measure more than thirteen mikres in length and twelve in breadth, mostly egg-shaped, with one broader and one smaller pole. These contain, mostly, a greater or smaller number of vacuoles and brownish pigment. These larger bodies are not alone situated between, but also in the interior of the liver cells.

When this dislocation takes place, the liver cells show degeneration in the form of clear round spaces, oftentimes melting together, as is seen in Figure 1, on the left side. If these spaces are all filled up with fat drops it can not be decided, the preparation having been treated with alcohol, but is not very probable, as the edges of these spaces are not infrequently ragged and irregular. Later only it seems to follow the deposit of fat, converting the whole protoplasm to a network with round meshes, as seen in Figure 2.

The question now arises, in what manner do the red bodies penetrate into the interior of the liver cells? Figure 1 gives the answer. In the second cell row from the right side we remark two small, red, oval-shaped bodies, measuring only two or three mikres in diameter, which lie imbedded in the bluish protoplasm of the hepatic cell, surrounded by a small clear space. If these foreign bodies, as may be suggested, are living organisms, one must suppose that the oval-shaped bodies, first developed in the leucocytes, lying in the interstitial tissue, may divide and penetrate, in their

earliest forms, into the interior of the liver cells, there growing more and more; they eat up and destroy the protoplasm of the liver cell. This destructive process results only in the demolition of the cell substance, which seems, in the commencement of the process, to be somewhat swollen, so that the lines of demarcation, principally in the radial direction, are effaced. The nuclei only show a slight proliferation and usually contain two or more nucleoli, often of excessive dimension.

It is very difficult to decide in which part of the interstitial tissue the oval bodies are primarily deposited. As the gall ducts and vessels seem to be free from them (I found such a body in a thrombosed central vein only once), it must be supposed that they are lying in the lymphatic spaces, which suggestion is supported by the fact that usually where the oval bodies are lying thronged in rows, leucocytes are present in the same spaces (Fig. 2), which show the usual form of lymphocytes, with great round, dark stained nucleus and small protoplasm.

Inflammatory processes are observed only in a small extension around the portal veins.

I am not informed as to the general conformation and aspect of the two livers examined, which gave me identical results, but I think that they were of the same aspect as described by Hamilton P. Jones as yellow, dead-leaf or boxwood in color, and bloodless (l. c., p. 460). Possibly they may have been flabby in this stage, with somewhat wrinkled surface; should this be so, the resemblance to some forms of acute yellow atrophy of the liver would be complete. But I will refer the question to the pathologic anatomists who have made postmortems in yellow fever cases. Possibly this affection will show the way to the detection of the true cause of these obscure diseases, so often originating from a seemingly simple catarrhal icterus.

The sharply defined form of these bodies, their different staining, their disposition in the interstitial tissue and in the liver cells, their forming of vacuoles and pigment in the more advanced stages, certainly indicate them to be parasites of the class of protozoa; but, having only dead material before me, I will not decide the question, unless they could be found in other organs in physiologic connection with the liver.

The spleen, pancreas and heart and the blood contained in these organs gave negative results. The stomach and duodenum always show deep alterations in yellow fever. "The mucous membrane of the stomach," says Jones, "was intensely congested, softened and eroded—the duodenum, as a general rule, presented the above conditions, intensified. This condition, however, in the majority of cases extended only down to the opening of the common bile duct" (l. c., pp. 459 and 460). What do our preparations show? We can only say, an intense gastritis and duodenitis, the latter more developed than the former, but the distribution of the emigration foci is of the same character in each. The infiltration of leucocytes always commences around the vessels, penetrating the superficial layer of muscle fibers. In the duodenum these infiltrations are larger and extend oftentimes to the surface of the mucous membrane. But in the two organs the higher parts of the interglandular tissue are filled up with small-edged cells, the nucleus not so deep stained as in the emigrated cells, fibroblasts (Ziegler) or hyperplastic connective tissue cells. The same oval-shaped and red staining bodies were always

present in the emigration centers of these organs, not in very great numbers, but never absent. The same were also found nearer the surface, in the hyperplastic part of the interstitial tissue, but seldom in a gland, and if present, were external to the epithelial cells (Fig. 3). But here another highly interesting form not present in the liver was also found, namely, nearly circular groups of small round bodies, stained in the same manner as the oval bodies. It may be remarked here, that all these bodies in the duodenum and stomach stain a deeper blue than in the liver. The red color is perceptible only after protracted decoloration.

I might suggest that these blackberry forms represent sporulation. If these spores, developed in the higher layers of the mucous membrane, are set free, they may penetrate into the mucous glands or lymphatic vessels and be transported by the way of the bile ducts or lymphatics to the liver, but this can only be ascertained in a postmortem examination. It seems very probable that the infection is transferred to the liver in one of these ways.

By these observations, to be completed by observation on the living and dead, we can very well understand the source of the disease, which is first a true gastro-duodenitis, remaining such in the milder, lingering or endemic cases of some countries, but the danger of the epidemic form commences with the immigration of the protozoa into the liver.

That the infection with these organisms, showing the nearest relation to coccidia and amebæ, which immigrate into the liver from the duodenum, deprives yellow fever of its terror, is natural, as watery fluids, fruits, vegetables and greens only can be considered as carriers of the infection.

The kidneys are always altered in the graver cases of yellow fever. In 202 cases of yellow fever observed by Jones, albuminuria was found in 125 of the non-fatal, and in all the fatal cases (45), in all 170, or 84 per cent. The amount of albumin varied from a trace to 80 per cent. Yellow stained casts and scanty urine were considered unfavorable symptoms, according to the same observer. The kidneys were generally a "brownish-yellow, larger and softer than normal, loaded with fat, and were generally intensely congested" (in the medullary substance probably). This is the general aspect in every septic kidney, very similar to the kidney in acute atrophy of the liver.

The microscopic examination shows no inflammation of the kidneys (it is wrong to speak of parenchymatous nephritis in these cases, as there is no proliferation of epithelial cells, nor any migrative process in the interstitial tissue). The convoluted tubules of the cortex alone show alterations, being filled up and vastly distended by a granular exudation; the epithelial cells here are ragged, and often compressed by the exudation. The glomeruli are free, and are also sometimes compressed by the same exudation. In many cases, casts were not formed in so great a quantity as is found in true nephritis.

This affection could be considered as a toxic one, but the differences in the effects on kidneys by true bacteria toxins is very remarkable, affecting the glomeruli in scarlatina (glomerulo-nephritis), and in Asiatic cholera promoting the destruction of the nuclei of the secreting epithelial cells (karyolysis). With exception of the exudation into the glomeruli and tubules, only the fatty degeneration of the cortex in phosphorus and other intoxications resembles this affection in yellow fever.

This condition indicates a true dissolution and hindered oxygenation of the blood, beginning in life; but we should expect then to detect free hemoglobin in the urine.

I will repeat, that this new theory of yellow fever, announcing the affection as a gastro-duodenitis, with consequent atrophy of the liver, originated by certain protozoa, must be supported by the examination of yellow fever patients. I hope to fulfil this task, but I think that we will now be better prepared to meet this work of high pathologic and hygienic importance to the United States.

SUMMARY OF PATHOLOGIC AND BACTERIOLOGIC WORK DONE AT ISOLATION HOSPITAL, NEW ORLEANS, LOUISIANA.

BY O. L. POTHIER, M.D.

Pathologist and Bacteriologist, Charity Hospital; Assistant Demonstrator of Histology and Bacteriology, Medical Department Tulane University.

NEW ORLEANS, LA.

In presenting this paper I will limit its scope to the pathologic conditions found, and to the bacteriologic work done with the cultures obtained from the cases of yellow fever at the Isolation Hospital, principally to corroborate the claims of Sanarelli.

The pathology comprises the examination of urine and the blood, the autopsies and the bacteriologic research of Sanarelli's bacillus icteroides.

There were 348 specimens of urine and 154 of blood examined, and 51 autopsies were held. The 154 specimens of blood represent as many patients from whom blood was taken and examined. The examinations of urine were made as they generally are in the pathologic department of the Charity Hospital, only they were made oftener as a guide in the treatment of the cases. Albumin was found in all the cases of yellow fever during the course of the disease. It usually appeared before the fifth day, seldom after. Bile was also present in all the cases, usually appearing before the albumin or concomitantly. Except in mild cases renal casts were found and include the different varieties.

Blood examinations were made in every case when possible. These were made: 1, to determine the presence or absence of the malarial hematozoon; 2, to determine the influence of yellow fever on the bacillus of typhoid, Widal's reaction; 3, to determine the proportion of red and white blood corpuscles; 4, to determine the changes taking place in the blood; 5, to determine special reaction of yellow fever blood with the bacillus icteroides of Sanarelli; 6, to determine the percentage of hemoglobin; 7, to make cultures from the living blood.

The malarial hematozoon was frequently found, especially during the period of convalescence. The variety most frequently seen was the crescentic form, which belongs more especially to the estivo-autumnal type of malaria.

Though Widal's reaction was tested in all cases when practicable it invariably gave negative results. The method employed was Johnson's modification of that of Widal, *e.g.* one part of dissolved dried blood to ten parts of an attenuated pure culture of bacillus of typhoid, and the time limit was fifteen minutes. The solvent for the dried blood was either sterile bouillon or filtered sterilized rain water. In all cases

of yellow fever examined the test was invariably negative, and the few cases in which a positive reaction took place was found to be typical cases of typhoid fever.

The blood count made in yellow fever cases never gave below 4,280,000 red blood corpuscles, and in one case that proved fatal gave 5,000,000 to 1 cubic millimeter of blood. The white cells varied from 20,000 to 4,660.

The changes in the yellow fever blood were studied in fresh preparations and in colored specimens, these last being colored with the Ehrlich's Biondi's stain, and others with an aqueous solution of methyl violet beta; for these stained preparations four cover-glass smears were taken from each patient. In the fresh preparations, as a rule, no alterations could be detected in the corpuscles. Occasionally the corpuscles appeared vacuolated and enated, but as these changes were more marked at the edges of the preparations and took place twenty to twenty-five minutes after they were made, these appearances were considered artificial and due most probably to evaporation and changes of temperature.

In the stained preparations the red corpuscles retained their normal aspect generally; occasionally a few vacuoles were found. The red corpuscles stained normally and the usual white corpuscles, lymphocytes, large and small, polymorphonuclear neutrophils, and eosinophiles are found. In a few specimens a few myelocytes were found, also normoblasts and extruded nuclei. I could not detect any increase in eosinophiles. In many of the preparations stained with methyl violet beta, these being made especially for the detection of bacteria, short rounded-end bacilli were found. Besides these, in a few preparations, long chains of slender bacilli were found associated with micrococci, usually in groups of two, and short rounded-end bacilli.

The agglutination reaction was applied to the following specimens of blood with the bacillus icteroides. The method employed was that of Wyatt Johnson, and the solution of dried blood was made in one series with sterile bouillon, and in the others with sterilized distilled water. In some, ordinary slides were used and in others hanging drops. The solution being one to ten the result was as follows:

Specimens examined on ordinary slides with sterile bouillon as solvent.

1. Ward No. 1, bed No. 2; preparation made at 4:08 P.M.; bacilli are less active at 4:55; no clumping at 5:00; a few clumps at 5:25 P.M.

2. F. Stellano; preparation made at 4:25 P.M.; bacilli are still active at 5:00; at 5:10 less active; at 5:18 P.M., clumping.

3. Chisolm; preparation made at 10:50 P.M.; examined until 12:10 P.M. without clumping or immotility.

4. Bed No. 9; preparation observed for thirty-two minutes; bacilli still active; slight clumping.

Second preparation from Chisolm prepared at 11:25 A.M.; observed until 12 M.: ringed with vaselin and then put into incubator until 2:40 P.M.; bacilli were still active; no clumps.

Third preparation from Chisolm at the same time, and solvent used being sterilized filtered water, and tested as above, the bacilli were found less active; no clumps.

5. My own blood, first preparation, solution one to ten made at 4:10 P.M.; observed twenty minutes ringed with vaselin; no clumping; bacilli active; put in incubator at 4:40 P.M.; next morning at 11:30 found majority of bacilli immotile.

Second preparation, one to five, made at 4:24 P.M.; observed fifteen minutes, ringed with vaselin; no clumping; bacilli active; put in incubator at 4:40; at 11:30 next morning majority of bacilli immotile.

6. Blood of Locassio, prepared at 11:15 A.M.; at 11:22 a few bacilli clumped; majority motile; at 1 P.M. put in incubator and examined at 4:45 P.M.; clumping still persisting; bacilli less active.

Ward No. 1, bed No. 9, made at 11:20 A.M.; at 11:27 some clumping; majority of bacilli motile; 12:02 P.M. bacilli still motile; examined until 1 P.M., when preparation was put in incubator and examined at 4:45 P.M.; bacilli less active; clumps persisting.

7. Frank French; preparation at 9:40 A.M.; examined for thirty minutes; bacilli forming; then small clumps; others motile; examined at intervals until 12 M., during which time bacilli were less active with clumps still persisting.

Hanging drops preparation:

8. Mary Stellano; first preparation; solution made with sterile bouillon at 4:40 P.M.; examined until 5:15 P.M., when a few clumps were noticed; other bacilli motile; examined until 5:25 P.M.; clumps persisting, while other bacilli were motile.

9. Will Kynion; preparation made at 10:22 A.M.; solution with sterilized distilled water, one to ten; examined until 1 P.M.; found bacilli clumping during that time, but bacilli in clumps are motile and majority of free bacilli motile; put in incubator until 4 P.M.; re-examined until 5 P.M.; clumping persisting; bacilli less active but still motile.

Mary Stellano; second preparation with sterilized distilled water, made at 10:35 A.M.; examined until 1 P.M.; clumping occurring, but majority of bacilli motile; put in incubator at 1 P.M. and re-examined at 4 P.M.; until 5 P.M. the clumps persisting and bacilli less active.

Locassio's blood; second preparation made at 4 P.M., as above; examined until 5 P.M., during which time slight clumping appeared; bacilli still motile; put in incubator and re-examined next day, finding persistence of clumps; bacilli less active.

10. Bed No. 25; preparation made at 4:04 P.M.; examined until 5 P.M.; no clumping; bacilli motile, and after being put in incubator were found motile next morning; no clumps.

11. Bed No. 9; prepared at 4:02 P.M.; examined until 5 P.M.; bacilli yet motile when put in incubator, and next morning found same condition; no clumps.

12. Bed No. 19; prepared at 4:22 P.M.; examined until 5:05 P.M., during that time a few clumps; found bacilli motile; put in incubator and re-examined at 9:30 next morning; bacilli motile though clumps persisted.

These are the only cases that I have had opportunity to test and the number is too small to allow any conclusions.

The percentage of hemoglobin was estimated with Gower's hemoglobinometer, using as a control test the percentage of hemoglobin obtained from one of the physicians of the hospital; this control gave 90 per cent. hemoglobin. The hemoglobin was tested in recent cases, during course of disease, and in convalescents. In the recent cases, and during the course of the disease the percentage of hemoglobin never exceeded 72 per cent., except in one case, which proved fatal, where it was found as high as the control, 90 per cent.; the lowest percentage in this series was 50. In convalescents the lowest percentage was 64 and the highest 80. These percentages show a decided loss of hemoglobin during the disease and a slow return to the normal in the convalescents.

The autopsies, fifty-one in number, are classified as follows: There were thirty-one in which none but the typical pathologic lesions of the disease were found; fourteen in which there were evidences of pre-existing chronic changes in the liver, the kidneys and blood vessels, these were more especially alcoholics; six that did not present any of the pathologic lesions of yellow fever. Of these last, one was a case of typhoid fever; the second one of general peritonitis from rupture of pus tubes; a third, general acute tuberculosis with chronic endocarditis, in an old negro man; the fourth, septicemia following pelvic peritonitis due to pus tubes; the fifth, tertiary syphilis; in this last case the culture tubes inoculated remained perfectly sterile; the sixth, was pneumonia in an alcoholic.

In all the autopsies from yellow fever cases the typical jaundice was uniformly present, more marked in some cases than in others, and the marked bluish

pink postmortem hypostasis about the dependent parts of body, face and neck was also noticeable. These appearances of the yellow fever cases formed a marked contrast with the other five, where the jaundice was not observed and the hypostasis less marked. All the tissues were generally found bile stained, in some instances very intensely.

On opening the bodies one of the first things that attracted attention was the marked fluidity of the blood contained in the heart and large vessels, and the congestion of the tissues.

The heart was usually full of blood, myocardium paler than normal, and fatty degeneration the rule. A special point of interest here was the intense congestion of the vasa vasorum of the large vessels at the base of heart, and also the congestion of the pericardium. In a few cases atheromatous changes of the valves of the heart and of the vessels were found.

The lungs were unusually free from chronic changes; the absence of tubercles, in the yellow fever cases, was the rule. In several where the mucous membrane of the trachea and bronchi was examined, it was found markedly congested, but not more than the surrounding organs.

The spleen was usually normal, except in a few cases where there was evidence of previous attacks of malaria, and chronic changes taking place.

The liver was generally found fatty, in some cases extremely so. The large vessels were usually dry but the portal capillaries congested to the extent, at times, of forming a marked delineation of the lobules. The gall bladder contained, as a rule, a small quantity of fluid and was seldom full. Besides these changes in the liver, in ten autopsies the organ was found cirrhotic.

The mesenteric vessels were generally full and gorged with blood and the different folds of the peritoneum universally congested. The mesenteric glands were usually normal.

The stomach presented the most characteristic congestion of its mucous membrane, which was swollen, red, eroded and contained hemorrhagic points in its substance. This congestion and changes, though universal throughout the organ, was more especially marked on the anterior wall of the organ and in the cardiac extremity, fading away as it reached the pylorus.

This congestion, less in intensity, extended as a rule to the mucous membrane of the duodenum, as far as the entrance of the common bile duct, beyond which it ceased in the majority of cases.

In a few cases the same condition observed in the stomach was found in the intestines, from cardiac extremity of stomach to rectum. In these the contents were of a dark meconium-like matter, of a black color and of very thick consistency. The same lesions found in the stomach were repeated in the mucosa of the whole intestinal tract.

The kidneys usually presented an acute inflammatory condition being congested, at times intensely so. In some cases infarcts were found, and also interstitial hemorrhages; these hemorrhages, usually small, attained in some the size of a pigeon's egg. Although generally in the substance of the organ, these hemorrhages were sometimes found in the pelvis and calices of the organ. The fatty degeneration was well marked, as a rule, and characteristic in its situation in the majority of autopsies. It was more marked in the cortex immediately at the edge of the malpighian

pyramids, forming arches around that border and radiating toward the cortex of the organ. In a few cases this degeneration was contrasted by the intense congestion in the same situation. This peculiar arrangement of the fatty degeneration was noticed in the first autopsy on a yellow fever case held in this city during the last epidemic and was afterward noted in every case. Out of the forty-five cases of yellow fever on which an autopsy was held at the Isolation Hospital this characteristic arrangement of the fatty degeneration occurred in thirty-five. In the ten remaining cases, I am told that it did occur, but as I did not find it recorded in the notes of the autopsies, I have not included them. Besides these marked changes, the kidney presented evidences of chronic changes in fourteen cases.

The brain was examined in only one case and the same congestion prevalent in other organs was also marked here. The meninges and surface of brain were intensely congested; the puncta vasculosa in the centrum ovale were decidedly marked and the whole organ was intensely congested; there was, however, no other sign of any inflammatory condition. The lack of time prevented us from making a more systematic examination of the nervous centers.

An average of five primary cultures were made at every autopsy; one from the blood of the heart and large vessels, one from the liver, one from the spleen, one from the kidneys and one from the lungs. In several cases, pieces from organs (liver, kidneys and spleen) were carefully removed and enclosed in anti-septic and aseptic wrappers and incubated for twelve to fourteen hours, and then inoculated in culture media.

As these did not give as a rule, any better results than the cultures obtained at autopsies, on account of the great loss of time entailed and the difficulty in transporting these pieces to the laboratory, the practice was abandoned. This made an aggregate of 255 primary cultures obtained from autopsies; of these a few remained totally sterile. Those that gave cultures were plated as soon as practicable after the autopsy. The primary cultures considered the best for the purpose were chosen for these plates, and cultures were made to test their purity. Several of these second cultures had to be plated over, in the attempt to eliminate the contaminating bacteria. The bacillus coli communis was found omnipresent, and difficult to eliminate, also in a few autopsies, a form of proteus with fluorescence. Several autopsies continued to produce the bacillus coli communis after several platings. The tests applied were the cultivation in ordinary bouillon, in peptone solution for the indol test, in litmus milk, in glucose and lactose bouillon, in gelatin, the plating of pure cultures, staining by Gram's method, replanting in tubes and inoculation of animals.

After having plated all the autopsies and recognizing that in several plates characteristic growths were present it was impossible to carry through all of them. I chose three that from their appearance and examination led me to believe that I had obtained a pure culture, and subjected them to the different tests described above, and carried on the experiments on animals with them. In all the different tests a pure culture of bacillus icteroides Sanarelli was used as comparison. These cultures, when subjected to the tests as described by Sanarelli, in his memoir, were found to be of slow growth in ordinary bouillon, showing a slight

cloudiness in twenty-four hours. It is a short automotile bacillus and produces marked fermentation in glucose bouillon; in lactose bouillon a very faint fermentation; in peptone solution, after twenty-four and forty-eight hours growth, gives no indol reaction, without addition of nitrites, and, when these are added, the reaction is very faint after twenty-four hours incubation; cultivated in litmus milk, even after twenty days incubation, there is no coagulation of milk and the color is not apparently changed; when subjected to Gram's method, they do not take up the stain.

In one of the autopsies (No. 40) the growth was obtained with difficulty, being exceedingly slow in ordinary bouillon, and on agar the growth was scant. This culture, inoculated in a rabbit, gave a pure culture more active and vigorous than the first, and after again subjecting it to the tests it was used as a pure culture giving better growths. These cultures in gelatin did not liquefy.

The experiments on animals were eighteen in number. In the inoculation of animals one is generally inoculated with a twenty-four hours bouillon culture of bacillus icteroides Sanarelli, as control, and the other or others with the same quantity of a bouillon culture of the same age, from the cultures to be tested.

The animals injected were two guinea pigs, fourteen rabbits and two dogs. Of these the two guinea pigs were injected with juice of organ mixed with sterile bouillon: No. 1 from juice of liver from autopsy No. 2; and No. 2 from kidney of same autopsy. The result is as follows: Guinea pig No. 1 was injected on Oct. 1, 1897, at 5 P.M., with 1.17 c.c. of an emulsion of equal parts of sterile bouillon and liver juice, in the peritoneal cavity. Animal did not eat at evening feeding; Oct. 2, 1897, did not eat and is quiet, does not care to move; at 12 M. animal in dying condition; at 12:30 P.M., found dead in cage, being nineteen and one-half hours after inoculation. Autopsy at 4:30 P.M.: postmortem rigidity marked; peritoneal cavity contains good quantity of fluid; membrane ecchymotic and congested; is smeared with purulence and the ecchymotic patches on diaphragm; lungs congested and ecchymotic; heart contracted and contains slight amount of blood; liver congested with ecchymoses in organ; kidneys, ecchymoses on surface. Cultures were made from different organs. Guinea pig No. 2, injected in same manner, presented same lesions.

Four rabbits were injected with pure cultures of Sanarelli bacillus icteroides: two with pure culture from autopsy No. 46, one with culture from postmortem No. 11, one from postmortem No. 6, two from autopsy No. 1, one from autopsy No. 40, two from autopsy No. 37 and one with Sternberg's bacillus X.

The four rabbits injected with Sanarelli's bacillus presented the following appearances at the autopsy:

Rabbit No. 2, weighing 1740 grams, injected Nov. 5, 1897, at 11:37 A.M., with 1.23 c.c. icteroides bacillus, seventh day bouillon culture, in vein of ear, died during night of November 6, and being found dead in its cage at 7 A.M. Autopsy at 8:20 A.M.: the weight was 1575 grams, being a loss of 165 grams from time of injection twenty-three and one half hours. Postmortem rigidity marked; small amount of fluid in peritoneum, otherwise normal; liver congested and studded all over with yellowish spots; on section, foci of suppuration were found; spleen full, enlarged and congested; kidneys congested and yellowish; heart filled with blood, organ somewhat pale; lungs intensely congested; urinary bladder contained 2 c.c. of urine, albuminous, with casts and renal epithelium.

Rabbit No. 3, needle having slipped, was injected in subcutaneous tissue of ear, Nov. 5, 1897, with 1.23 c.c. of bacillus icteroides. It died during night of 10th. The same yellow spots appear in liver as were found in No. 2; spleen congested;

kidneys appear smaller; heart and lungs apparently normal; urinary bladder greatly distended, contains 25 c.c. of urine; stomach contracted and contains no food, but a dark brownish fluid, walls apparently normal; had convulsions before death. Urine contains 20 per cent. moist albumin, hyalin and granular casts and renal epithelium.

Rabbit No. 8, weighing 1485 grams, injected Dec. 19, 1897, with 4.5 c.c. of a twenty-four hours bacillus icteroides in bouillon, died Dec. 20, at 5 P.M. At autopsy, December 21, 9:30 A.M., weight 1470 grams; rigidity marked; conjunctiva injected; lungs, petechiae on surface and congested; heart, petechiae on surface and congested at base, filled with partly fluid blood; liver congested, some yellowish discoloration disseminated throughout organ; spleen congested and enlarged; kidneys congested, yellowish spots throughout organ; bladder contains 10 c.c. albuminous urine and gives reaction of bile; stomach, mucosa intensely congested, swollen, petechiae in mucosa and eroded, especially marked around cardia; all tissues are intensely congested.

Rabbit No. 11, weighing 1827 grams, injected Jan. 1, 1898, at 11 A.M. with 5 c.c. bacillus icteroides bouillon culture sixteen hours old, died at 10:30 A.M. January 18; postmortem same day. Postmortem rigidity marked; subcutaneous connective tissues intensely congested; heart filled with black fluid blood; liver congested; spleen intensely congested and enlarged; kidneys congested; stomach is intensely congested and contains blackish brown fluid mixed with food. During life conjunctiva were intensely congested.

Rabbits No. 6 and 12 were injected with cultures from autopsy No. 46. No. 6, weighing 1780 grams, injected at 11:40 A.M., Dec. 19, 1897, with 3.5 c.c. of 24 hours bouillon culture, from postmortem No. 46, died between 8 and 9 A.M., December 20, weighing 1735 grams. Autopsy that A.M., showed rigidity marked; conjunctiva injected, can see through cornea streaks of injected vessels; gums, small red lines over incisors; lungs, petechiae on surface; heart filled with fluid blood; liver congested, organ appears granular from the intensity of the congestion; gall bladder empty; spleen congested and enlarged; kidneys congested with petechiae on surface, contains whitish yellow spots, stomach mucosa intensely congested and contains petechiae and erosions filled with food; urinary bladder distended with 16 c.c. albuminous urine. Rabbit No. 12, injected with same culture presents same lesions Jan. 16, 1898.

Rabbit No. 1, which was injected with culture from autopsy No. 6, did not present any characteristic lesions, except the liver, which contained a large number of yellowish foci resembling tubercles undergoing cheesy degeneration: spleen normal in size.

Rabbit No. 4, injected with a culture from postmortem No. 11, presented nothing of mark, except the same lesions of the liver as were found in rabbit No. 1, and in both the urinary bladder was empty.

Rabbits Nos. 7 and 13 were injected with a culture obtained from postmortem No. 1.

Rabbit No. 7, weighing 1680 grams, was injected Dec. 19, 1897, at 12 M. with 4 c.c. of twenty-four hours bouillon culture from postmortem No. 1, died between 8 and 9 A.M. Dec. 20, 1897, weighing 1650 grams. At autopsy which was held the same morning, postmortem rigidity marked; conjunctiva congested; heart filled with partly fluid blood, congested at base; lungs congested, marked petechiae, which are large; liver congested and many yellowish spots, capillaries congested; spleen congested and enlarged; kidneys are congested and appear swollen, some yellowish discoloration; stomach mucosa intensely congested, contain petechiae, especially around cardia; duodenum, mucosa swollen and markedly congested; urinary bladder distended with 20 c.c. albuminous urine which gives bile reaction. Rabbit No. 13 gives same lesions.

Rabbit No. 14, weight 2151 grams, was injected Jan. 15, 1898, at 11:40 A.M. with 5 c.c. bouillon culture sixteen hours old, from postmortem No. 40, and died during the night of January 20, weighing 1930 grams. Postmortem January 21, at 12:30 P.M., showed pericardium very much congested; heart dilated and filled with fluid blood; spleen congested and enlarged, of dark color; liver congested, appears enlarged and contains yellow spots throughout, probably fatty degeneration; kidneys congested; lungs very much congested; stomach intensely congested.

Rabbit No. 10, weighing 1551 grams, was injected Dec. 27, 1897, with 3½ c.c. bouillon culture twenty-four hours old from postmortem No. 37. For several days thereafter temperature ranged from 105 to 106 degrees; never had bile nor albumin in urine, which was obtained by catheterization; became cachectic and emaciated, and on January 8, could not stand up. January 9, it was chloroformed to death. The weight was 1300 grams; all organs appeared pale but did not present any marked

changes: stomach contained food and was normal; bladder extremely distended with urine, but could not measure quantity as it ruptured on opening animal.

Rabbit No. 5, weighing 1130 grams, was injected Nov. 5 1897, at 11:27 A.M., with 1.23 c.c. of a twenty-four hours bouillon culture of Sternberg bacillus X. Twenty-four hours after the animal was sick, refused to feed and remained quiet, and after forty-eight hours began to eat some, but was still quiet and did not care to move. Emaciated gradually and became unable to stand up November 21; died on the 25th. At autopsy animal was found very much emaciated: liver contained a few small yellowish spots disseminated through the organ, which was red: heart filled with clotted blood; lungs dark red; spleen normal; kidneys swollen; stomach contains food; gall bladder distended, urinary bladder contained 50 c.c. urine, which was not albuminous.

Rabbit No. 9, though injected, is still alive and has a small abscess of ear. Was injected with culture from autopsy No. 37.

From the foregoing it will be seen that the cultures obtained from autopsies Nos. 1, 40 and 46 give the same lesions as that of the bacillus icteroides of Sanarelli, and these three cultures also give the same bacteriologic reaction when submitted to the different tests characteristic of the bacillus icteroides.

Besides these rabbits two dogs have been inoculated.

Dog No. 1, unfortunately, died of chloroform narcosis while he was being injected, but is interesting on account of the rapidity with which the bacilli were disseminated through the organs. He had been injected in a vein of the hind leg, and five minutes hardly elapsed between the time of injection and the time that the organs were reached, during the autopsy, yet all the organs gave pure cultures of bacillus icteroides and the blood from left heart was found swarming with bacilli.

Dog No. 2 was also injected Jan. 11, 1898, with 5 c.c. of a 72 hours bouillon culture of bacillus icteroides, partly in the circulation and partly subcutaneously, as the animal moved and the needle slipped out of the vein. During the first twenty-four hours it was sick and nauseated: temperature reached 105 degrees, but it gradually recovered, and on January 16 was re-injected subcutaneously with 10 c.c. lactose bouillon culture bacillus icteroides. It became sick as at first, but to a less extent. After three or four days it had sufficiently recovered to break loose from its place of confinement and was allowed to escape.

With the exception of two, the cultures made from living blood obtained from ten patients remained sterile. The blood was obtained from the veins of the patient through a sterilized glass syringe. One or two c.c. were drawn and immediately inoculated from the syringe into culture tubes. One specimen was obtained from a patient that was bled and several tubes inoculated. Of these two cultures obtained from the blood we have not yet obtained any definite results.

From the foregoing we may conclude:

- 1, that albuminuria and presence of bile in the urine is a constant symptom in yellow fever, appearing about the fourth day in mild and earlier in severe cases;
- 2, that the presence of the malarial hematoozon does not preclude the possibility of yellow fever;
- 3, that in solutions one to ten the yellow fever blood does not give any reaction with pure cultures of the typhous bacillus;
- 4, that if we except the diminution of hemoglobin, the blood does not show any marked changes;
- 5, that the most characteristic pathologic changes in the organs are the marked stentosis and congestion of liver, kidney and heart, the marked congestions, erosions and hemorrhages of the stomach and intestines and, usually, absence of lesions in the spleen and lungs. The other tissues present a marked icterus and congestion;
- 6, that the bacillus which we isolated and with which we have experimented is identical with that reported by Sanarelli as the bacillus icteroides, and the results obtained would justify us in considering it the special cause of yellow fever.

NEUROTIC ECZEMA.

Presented to the Section on Cutaneous Medicine and Surgery at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY L. DUNCAN BULKLEY, A.M., M.D.

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL; CONSULTING PHYSICIAN, NEW YORK HOSPITAL, ETC.

NEW YORK, N. Y.

The recognition and management of eczema must ever be an interesting and profitable study to the physician, because practically it forms a very large share of the cases of skin disease coming under his care. Even in dermatologic practice, where the rarer diseases and also the minor ailments of the skin contribute to make a considerable proportion of the whole number, it constitutes nearly one-third of all cases. In a recent analysis of 10,000 miscellaneous skin cases in the writer's private practice, there were 3201 patients with eczema, they forming 32.01 per cent. of the whole number. In ordinary private general practice, where many infantile cases occur, this disease undoubtedly forms over one-half of all the cutaneous diseases coming for treatment.

Neurotic eczema is particularly interesting to the general physician, because if recognized and rightly treated not only are the results commonly very satisfactory, but the patient also receives much improvement in general health by the measures calculated to benefit the eczema. Neurotic eczema should always be recognized as the signal flag of danger and should never be passed over with attempts to gain relief from local treatment alone, which can only be of minor and temporary benefit.

The influence of the nervous system in the production of skin lesions of various kinds has long been recognized and is now abundantly established, both by pathologic and clinical proof. Its influence in producing and prolonging eczema was very fully elaborated by the present writer some time ago, and reference will here be made to some of the evidence then collected, as well as to more recent clinical experience.

Neurotic eczema is seen in both sexes and in all ages, from the cradle to the grave, although it is much more common in certain periods of life than in others. In infancy it is frequently observed in connection with cutting of the teeth, fresh eruptions occurring as each new tooth presses on the swollen and tender gum. In childhood it is less common, but may appear with each occurrence of nerve-strain, whether from overwork in school or over-excitement in recreation. The same is true in youth, where the changes of puberty come in as a factor, especially in females. But its most frequent time of occurrence is during that active period of existence between 20 and 55 years of age, when the strain and burden of life falls heavily on so many and when the strongest constitutions too often show many evidences of breakdown, both in the nervous system and in other directions.

Something can be learned of this from the following tables. The first relates to nearly 6000 cases of eczema, occurring among 20,000 miscellaneous skin cases in my public and private practice. The second table is constructed to show the percentage of eczema patients at different periods of life, as compared with the number of individuals alive at the same age, as shown by the life tables of insurance companies.

"On the Relation of Eczema to Disturbances of the Nervous System."
—Medical News, Philadelphia, Jan. 31 and Feb. 7, 1891.

TABLE 1.—Ages of eczema patients.

75 to 80 years . . .	1.5	0.8	-0.7
80 to 85 years . . .	0.7	0.2	-0.5
85 to 90 years . . .	0.2	0.08	-0.12
90 years and over . . .	0.07	0.05	-0.02

Examining these tables it is interesting to note the sudden increase in the frequency of eczema during the period from 20 to 25 years of age, and the continuance of the large number through those of 50 and 55 years in spite of the diminishing numbers alive at the advanced age. By the second table it will be learned that the greatest actual percentage of cases of eczema, in comparison with the individuals living, after the first year of life, was in the period between 50 and 55, where it was represented by +2.3, while between 60 and 65 years the percentage was exactly equal; in the period between 10 and 15 years the disease is relatively the least frequent, the difference being represented by -4.8.

It is also interesting to note the large increase in the number of cases in females, in private practice, between 20 and 25, where they form nearly 11 per cent. of all the females, whereas the males at this same period form only a little over 5 per cent. of the class. During the two decades, between 20 and 40 years of age, when the strain of life is the greatest, there were no less than 1947 cases of eczema, or almost exactly one-third of the entire number; this is the more

remarkable considering the very large number seen in the first years of life, and the diminished proportion of persons living during the later period, as shown in Table 2.

Various forms or phases of nerve disturbance are seen in connection with neurotic eczema, and they may be considered under the following heads: 1. neurasthenia, or nerve exhaustion; 2. nervous and mental shock; 3. reflex phenomena; a, of internal origin; b, peripheral; 4. neuroses; a, structural; b, functional.

1. *Neurasthenia or nerve exhaustion.*—First in importance, both from its frequency and its seriousness is nerve strain, which is a fertile cause of neurotic eczema. In many cases the direct connection may not always be immediately traceable, but watching the same patient for a length of time it will be found that with each period of nerve exhaustion, from varied causes, the eczema crops out. I can not do better than to quote a few illustrative cases which I reported in the article previously alluded to.

An unmarried lady, aged 53 years, was the executive officer of a charitable institution, and her duties were arduous and exacting. On Tuesday of each week she was particularly tried on account of the weekly meeting and inspection of a board of lady visitors, and that night was often sleepless. Her eczema of the face and hands was always aggravated on the succeeding morning; indeed, the eruption, which would often yield very satisfactorily to treatment during the week would burst out afresh on the Wednesday morning succeeding the visit. This had been the case for some months before I saw her and was verified by myself again and again.

A prominent clergyman, aged 52 years, had for many years an eczema of the head and face, which was always greatly aggravated on Monday after the Sabbath's mental work and strain. This I observed on a number of occasions, the eruption greatly improving each week until Monday, when he would present himself with an aggravation of the eruption. The same occurred sometimes during the week, whenever extra work, as a public address, was called for, and has been repeatedly observed in other patients since.

In another case, that of a lady, aged 22, any nervous excitement, or household disturbance and hysteric crying, would be followed by a fresh outbreak of eczema on the hands.

Since these cases were reported I have seen a number almost as striking, and have frequently observed business and legal worry followed shortly by eczema. Mentioning the matter to an exceedingly intelligent gentleman, aged 47 years, whom I have attended in attacks of eczema for ten or more years, he remarked on the truth of the observation, and said, "you may quote me as a striking illustration of the effect of nervous strain in producing eczema again and again."

While writing this article, a gentleman aged 60, who has had eczema occasionally for fifteen or more years, also corroborated this statement very strongly.

Prolonged and severe household strain will produce the eruption repeatedly, in women, and continued loss of sleep, often only from sickness in others, will now and again be followed by eczema. My notes show numerous cases where the nervous exhaustion following the grip caused the eruption to appear.

2. *Nervous and mental shock.*—The effect of nervous shock and violent emotions, such as grief, anger, etc., in the production of eczema has long been recognized by writers on dermatology, and the well authen-

ticated instances of this on record are so numerous that it can not be questioned that this form of nervous disturbance often operates either to produce the disease or to excite an attack in one susceptible to the same. A single very striking illustration may be cited from Leloir,² a most careful authority.

"A young woman who never had any eruption previously, except a pustular disease of the scalp, at 2 years of age, but who was very nervous and impressionable, and who was in perfect health, suffered a mental shock as follows: Approaching her home she saw her little child leaning out of the window, and on the point of falling; she cried out, and the child being startled let go her hold and fell, strangely enough, directly into the mother's arms, so that it received no harm. But the mother lost consciousness, and was completely broken down by the shock, and within three days developed a sharp attack of eczema, beginning on the upper extremities and invading much of the surface. Some time afterward she had a second and a third attack, each time following mental disturbance."

The same writer records several similar cases and Tommasoli³ reports the occurrence of eczema after long grief and sudden shock.

Mental and moral shock occurring in many different manners have been observed to be followed quickly by attacks of eczema. Thus Radouan⁴ reports that cases occurred in immediate consequence of the siege and commune of Paris, in 1871, and I saw more than one case ascribable to the financial panic in Wall Street, known as "Black Friday" several years ago.

3. *Reflex phenomena.* (a) *of internal origin*, (b) *peripheral*.—The influence of reflex irritation in the production of disease has long been an established fact, although opinions have varied in regard to details and individual cases.

Many writers have related cases illustrative of the production of eczema by this means, and in certain directions it is of not very infrequent occurrence. This reflex irritation may come from within, from some other organ, or part of the system, or it may result from external irritation of the skin; in either case the eruption excited may cease with the removal of the cause, or may persist indefinitely.

(a) *Reflex eczema of internal origin*.—The most common illustration of this is the eczema observed in teething infants, where each accession of a tooth will cause a fresh outbreak of eruption on the cheeks, forehead, chin, or elsewhere. Another rather frequent form of reflex eczema is seen in that accompanying eye troubles. Many have reported cases of the eruption, which were cured by wearing proper glasses. I saw a very striking instance in a lady aged about 50 years, in whom attempts to use the eyes has repeatedly precipitated attacks of eczema of the lids and chin, also on the forehead. Intestinal irritation has been observed to produce attacks of eczema, and also tapeworm and the oxyuris. Menstruation is likewise a frequent exciting cause as observed by Danlos⁵ and others, and as I have repeatedly witnessed.

(b) *Reflex eczema of peripheral origin*.—This form of disturbance is more difficult to make out, but a number of observations are on record where severe

cutaneous irritation, as burns, etc., were followed by eczema. Scratching is a fertile cause of eczematous eruption in those predisposed thereto. Not only does this result from the direct scratching of an affected part, but the irritation of a certain part by scratching or otherwise can excite a reflex irritation in a distant part, which may be followed by eczema in that locality.

4. *Eczema dependent upon neuroses*, (a) *structural*, (b) *functional*.—Eczema has been observed to follow structural nerve changes, as after injury, amputations, etc., and also in connection with functional neuroses, as neuralgia. It is not necessary to develop this part of the subject greatly, but I will mention one case where the connection of eczema and neuralgia was very marked.

Mrs. B., a widow, aged 30 years, was thrown on her own resources for the support of her mother and herself. She took to literary pursuits, and became the editor of a magazine requiring a large amount of personal work, she using the pen almost constantly. After some months she began to suffer from neuralgia of the right arm, and at the same time a papular eczema developed on the back of the arm and radial side of the forearm, attended with the most intense itching. When she ceased for a time from her great use of the hand the neuralgic pain lessened and the eczema diminished, but a return to her severe mental application would cause a return of both. This continued for some time, and treatment for either condition seemed to have very little effect while the arduous labors were persisted in, but both yielded when work was relaxed or suspended.

We have now reviewed some of the principal relationships of eczema with nerve disturbance, but the subject is a very much larger one than would appear from what has been said. The literature of it has already reached very large proportions and has hardly been alluded to. But enough has been said to show clearly the importance of the subject. We will now consider some of its more practical aspects.

Neurotic eczema does not differ very greatly from other forms of the eruption, but a trained eye can generally suspect the true character of the case.

The eruption is apt to come first upon the hands and face, less commonly on the feet. But from its starting point it may extend over large surfaces, and after scratching, or irritation by treatment, may present quite the features of gouty eczema.

Neurotic eczema on the hands is very apt to exhibit vesicles, but on the adult face the eruption is quite as likely to assume and maintain the erythematous form, without vesicles, and often without moisture, unless scratched. The groups of lesions of neurotic eczema have a tendency to be pretty sharply defined, in more or less herpetic patches which may present mainly solid papules, or, when torn, a raw surface. The areas affected early in the eruption are not apt to be very large, but the eruption is composed of a number of patches of aggregated lesions.

Neurotic eczema is intensely itchy, and the patient will often scratch where there are no apparent lesions, and so develop the eruption in one place and another. The scratching indulged in is commonly of the most severe kind, it seeming almost impossible to reach the seat of the trouble until the deepest portions of the epidermis are reached. The spasms of itching are sometimes fearful and utterly uncontrollable. I remember the case of an elderly lady whose two

³ Tommasoli: Monatsh. für pract. Dermatologie, 1886, p. 432.

⁴ Radouan: Etude théor. et pract. sur l'Eczema. Thèse de Paris, 1875, p. 41.

⁵ Danlos: Etude sur la Menstruation, etc., Paris, 1874.

daughters were not able, when the spasms seized her, though they used much force, to prevent her tearing her face and neck till the blood literally ran down, which I witnessed at my first visit.

Treatment of neurotic eczema.—This will often tax the patience and skill of the physician to the utmost, and the broadest principles of medical knowledge and judgment will often need to be put in operation and maintained, if the patient is to have great and permanent benefit. The treatment includes both constitutional and local measures: the former are essential, the latter are helpful.

Constitutional treatment.—Naturally every case requires to be studied and treated on its own merits; no two cases could be treated alike from beginning to end.

There is some danger of error, in approaching a case of neurotic eczema, in supposing that because of its nerve element it will require at once, and mainly, drugs which are known to have an influence on the nervous system. At times the treatment may be that of ordinary gouty eczema, for neurotic symptoms are exceedingly common in gouty subjects, and often largely dependent upon an existing gouty state, and unless that element is reached and rectified the progress will be poor. The strictest attention should be paid to the digestive system, the action of the bowels and kidneys, and above all to the diet; and this should be done, not only at the first visit, but on each subsequent consultation, and proper remedies and measures continually given.

But in all the treatment there is to be a continual regarding of the nervous system, and use of remedies and measures calculated to strengthen that. Arsenic undoubtedly finds an important place in the treatment of neurotic eczema, but should never be relied on alone, and I seldom administer it in the form of drops, the Fowler's solution so universally given by the profession for every case. Iron, nuxvomica or strychnin, quinin, the phosphates, ergot, oils, and many other remedies may come into play in the management of the disease. In occasional cases much benefit will be obtained from digitalis in strengthening and regulating the capillary system, and so improving nerve and cellular nutrition, while other cases will require the sedative action of aconite in proper and free doses.

A few words may be added in regard to the attempt to give relief to the itching and securing sleep in neurotic eczema, by the administration of internal remedies, hypnotics. While the eruption is in an aggravated condition, it often seems almost impossible to effect much by this means. Opium and its preparations only aggravate the itching, and if sleep is secured it is of an entirely unrefreshing character. Codeia seems to be the least injurious of them all. Sulphonal and trional in large doses will sometimes be effective, but are often followed by further nervous exhaustion, in the end aggravating the complaint. Phenacetin in full doses, repeated in an hour or so, will sometimes prove most effective, and antifebrin, with hot water and a trifle of whisky, will often secure very refreshing sleep; in milder cases urethan in one gram doses is effective. Tincture of gelsemium, given in repeated and increasing doses, even every half hour, has in some instances proved most serviceable in my hands, as also cannabis indica. The bromids have relatively little effect, although when combined with a very small dose of morphia

and aconite, have at times proved very valuable. A large warm drink at bedtime will often aid these remedies and may be valuable alone.

The diet must always be carefully directed. Not only should ordinary rules be given as to the avoidance of unnecessary and injurious articles of food and pleasure, which by deranging the digestive system, can greatly hinder the progress of the case, but the diet should be so arranged that it shall furnish the best possible nerve nutriment, and in a form easily assimilable. For this purpose I always order an increase in the digestible fatty matter and phosphates. Some caution may be required in regard to the former, but with a little care the amount of the fat of meats and oils, and also fresh butter, can be added to the dietary. Articles commonly called greasy, or where the fat is combined with starchy matter, as in pastry and fried articles, are to be avoided, but well browned bacon is often a very valuable addition to the meal. The phosphates are found abundantly in the preparations of whole wheat, such as crushed wheat, wheaten, wheatlets, wheat germs, Pettijohn's breakfast food, etc., as also in bread made from the whole wheat flour, some of which should be taken if possible three times daily. Fresh fish (not fried) is also serviceable.

But the one article which contains the elements necessary to nourish the nervous system and proves of the most signal advantage is milk, if properly taken. This should not be used at all with meals, nor after or in connection with the least particle of food, otherwise it undergoes caseation and may embarrass the liver, which is too often at fault in these cases. My plan is to have the milk taken warm, pure and alone, one hour before each meal, and also at bedtime, if sufficient time has elapsed for the stomach to be perfectly empty, which is at least four hours after a hearty meal. When the digestion is sluggish, and the milk meets the late products of digestion, it is curdled and then its digestion requires some considerable time and we do not get the benefits desired. But if it can be taken on an absolutely empty stomach, when the alkaline tide has already set in, it is then absorbed almost immediately and affords a refreshment to the whole system, including the nerve elements, which can hardly be obtained in any other way, and which must be observed to be thoroughly appreciated. It is understood that this precludes the possibility of adding liquor or an egg to the milk, and especially should there never be a cracker or anything else eaten with or near it. When taken in the manner described not only does it not diminish the appetite, but increases it; whereas if by any chance the milk has become caseated in the stomach, the necessary digestion may, and generally does, impair the appetite, as well as disturb the liver action. This plan I have followed for many years, in hundreds of cases, and I am very positive of the vast benefit resulting, when it is strictly carried out.

Local treatment.—The indications for local treatment differ so materially in different cases that it would be impossible within the limits of this paper to afford even the briefest outline of all that might be required; a few practical hints, however, may be given.

First, there is danger of doing too much in the attempt to get relief from the itching, which can seldom be obtained by local measures alone. The plan of treatment should be a soothing and protective one, and the mildest applications should be made first. Zinc ointment with 1 or 2 per cent. of carbolic acid or

creosote, or with 5 to 10 per cent. of ichthyol, or tincture of camphor, is always a safe and generally beneficial dressing if well and thoroughly applied. But to be of service it should be kept thickly applied, spread on a lint in most places, and bound on firmly. In the acutely inflamed and especially in the erythematous forms of the eruption, there is nothing better than the well known calamine and zinc lotion, freely sopped on many times in the day. Ichthyol in watery solution, 10 to 20 per cent., freely bathed on the part, often gives great relief, or if the skin is too dry it may be used in oil in the same strength.

On more chronic patches the permanganate of potassium, 2 per cent. solution in water, painted over the part will sometimes arrest the itching very well; it may either be used alone, or the calamine and zinc lotion may be sopped on after the surface has dried, or an ointment may be applied if the skin is at all hard.

In the erythematous eczema of the face a tannin ointment, 1.95 to 3.9 grams, to the 31.2 grams, with 2 per cent. of carbolic acid is effective; a mixture of camphor, 1.95 grams to 31.2 grams of zinc ointment also forms a good antipruritic. In still more chronic states the tar and zinc ointment, as recommended by the present writer many years ago, when thickly spread on lint and bound on, will often also serve admirably to control the itching.

The use of very hot water for a brief application, followed by an appropriate ointment, should never be forgotten. In old cases of eczema of the scrotum the effect of this treatment is sometimes very remarkable. Menthol will often prove a valuable addition to ointments, in the strength of 2 to 4 per cent., with about half as much carbolic acid, which latter serves both to heighten the antipruritic effect and also to overcome some of the chilly sensation caused by the menthol.

In bringing this brief and rather imperfect study of neurotic eczema to a close, I wish to again emphasize what was intimated early in my remarks; namely, that I do not regard eczema as a local condition or disease of the skin, but that it has constitutional and general relations which should always be considered and studied. The neurotic relations of eczema are especially interesting and important because of the excellent results which follow a careful and correct appreciation, interpretation and treatment of them; whereas, a neglect of this aspect of these cases will lead not only to their chronicity and rebelliousness, but also to an injury to the patient and further nerve exhaustion, whose ultimate result may be most deplorable.

4 East 37th St.

DISCUSSION.

Dr. SCHAMBERG—I will narrate briefly the history of a case of neurotic eczema. A young woman suffered great mental strain nursing her husband through a protracted illness. His death was a shock which prostrated her entirely. She thereafter suffered from a profound neurasthenia which lasted for a considerable period of time. She subsequently became restored to health by taking a rest cure. This woman consulted me for a recurring papular eczema of the hands and forearms. A peculiarity of this case was the extremely rapid evolution of the lesions. During an attack of mental excitement the papules would spring up almost under the eye of the observer. They were closely aggregated in patches and were intensely itchy. They disappeared in as short a time as they appeared. A noteworthy fact in this case is that a hysterical daughter was also the victim of eczema. There would thus seem to be an apparent tendency to heredity in this case.

Dr. FLEISCHNER—I saw a case of a young man of phlegmatic temperament, all depressing nervous elements entering into the disease of no apparent import. No treatment constitutional or local had any effect. It was found out indirectly that he was

engaged to be married, and on being advised to ignore his disease altogether and fix a date for the wedding, his eczema abated without further treatment from the day of this advice being given. It is held that whenever the cause can be removed that alone will overcome the disease and unless that is done no amount of local or constitutional treatment will be of any but the most meager effect.

Dr. RAVOGLI—I had an experience with one patient who, whenever he smoked a cigar had an attack of eczema scroti.

Dr. BULKLEY—Tobacco will sometimes occasion attacks of eczema and I have repeatedly known it to be the cause of a relapse.

MYCOSIS FUNGOIDES; WITH REFERENCE TO A CASE.

Presented in the Section on Cutaneous Medicine and Surgery, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY JOHN V. SHOEMAKER, M.D., LL.D.

PHILADELPHIA, PA.

A married woman, 60 years of age, who, upward of a year ago, was for some time under my care, gave the following history: The disease from which she suffered began four years and three months prior to her first visit. The first manifestation occurred in the form of red patches situated upon the back. They were accompanied by intense itching. They were rather bright in color. From the back the lesions gradually spread to the breast, abdomen, neck and limbs, attacking even the soles of the feet. Some, after a certain degree of development, healed. According to her statement, the skin had been more seriously affected than it was at the date of the examination. Itching had throughout been a prominent symptom. The lesions were also the seat of considerable pain. They often bleed when rubbed or scratched.

The patient's appetite was poor, she was habitually constipated, and had lost flesh. She suffered also from insomnia. No case of inveterate skin disease had ever occurred in any member of her family. The patient is ignorant of any cause of this disease. When examined, Dec. 20, 1895, the greater part of the woman's body was found to be covered with patches and tumors of various sizes and stages of development. The face was comparatively free. A red, infiltrated patch was present upon the right upper eyelid. The thyroid gland was decidedly enlarged, more particularly upon the right side. The goiter had existed for many years before the appearance of the skin disease. Upon the skin covering the gland were several fungous excrescences. Numerous similar outgrowths were situated upon both sides of the neck. The upper part of the chest, the mammary glands, abdomen, and axillæ were extensively diseased. It is scarcely possible to describe the lesions in detail for the reason that their numbers, size and proximity left but little of the surface unaffected. The lesions consisted of patches and tumors. The former were of various sizes and shapes, of rather a bright red color, and more or less elevated. The latter were prominent outgrowths, some bright and others rather dark red, excoriated and often bleeding. They were broad at the base. A growth about four inches in average diameter, the base of which was rather oval than circular in outline, was seated upon the upper part of the left breast immediately in front of the axilla. Upon the right breast, in a nearly corresponding situation, was a long, oval, slightly elevated, bleeding patch. The anterior and posterior surfaces of the arms and forearms were studded with patches. Upon the back the lesions, though abundant, were not as

numerous as upon the front of the body. Behind the right axilla there was a large fungous tumor. Upon the right side a similar large mass was observed. The largest tumors were found in the groins. They were of the same character as those already described, raw, bright red, fungous and bleeding at the slightest pressure. Upon the buttocks, thighs, calves, legs and feet elevated patches and excrescences were abundant. On account of the excessive itching the surface of the lesions were constantly torn, irritated and bleeding.

The patient lived at a distance, but visited me at stated intervals for perhaps eight months. During

epithelial elements, each extending through the entire depth of the section of the specimen, dividing in some portions into epithelial columns with occasionally small interspaces. At and near the surface the epithelial cells are large and somewhat decreasing in size from surface or margin as we descend into the body of the tumor, forming irregular cell columns and collections or nest-like arrangements."

The foregoing account certainly depicts an unusual condition of the skin. The existence for several years of prominent lesions of so extensive and well nigh universal distribution, with such slow decline of the general health, is not in consonance with our experi-

Mycosis Fungoides (from Nature).

this period the disease seemed at times to improve, but relapse invariably followed. The general health slowly declined and the patient succumbed in the summer of 1896, during my absence from home.

The report of a microscopic examination of pieces taken during life from the tumors, reads as follows: "Scrapings of the surface showed single epithelial cells of the squamous variety, together with some column-like cells with indistinct concentric rings or layers. Section revealed that the tumor was made up for the most part of epithelial cells with a vascular connective tissue, stroma or framework supporting the

ence of malignant disease or severe infectious processes. The microscopic examination was suggestive neither of syphilis nor tuberculosis. The abundance and arrangement of epithelial cells and the presence of a fibrous stroma points rather to carcinoma, but we can not admit the possibility of so many cancerous tumors existing for several years upon the surface without causing visceral involvement and cachexia. If, therefore, we are unable to place implicit dependence upon the revelations of the microscope, it only remains for us, relying upon the clinical manifestations and natural history of the case, to pass in review

those diseases capable of producing large and numerous fungous growths.

1. *Syphilis*.—The lesions undoubtedly bore no resemblance to the ordinary manifestations of syphilis. Nevertheless, the latter disease does sometimes give rise to fungous growths. Moist papules or mucous patches may sprout luxuriantly, but they do not cover the entire surface. The ulcerated tubercular syphilide may also assume the appearance of a vegetating growth, but this transformation is limited in locality and not so widely generalized as in the case which I have described. Furthermore, there was neither a history nor preceding evidence of syphilis. In doubtful cases we are accustomed to rely with some confidence upon the touch-stone of treatment. In this case anti-syphilitic treatment revealed nothing; it caused not the slightest improvement.

2. *Frambesia*.—Syphilitic excrescences sometimes assume a berry-like form to which the name "frambsioid" syphilide has been applied by some writers. The disease, whose lesion is distinctively likened to a raspberry, is frambesia, or yaws, endemic in certain tropical countries, and occasionally seen in our extreme southern States. My patient had never lived farther south than Pennsylvania. The lesions of yaws are not so widely distributed, do not itch, frequently cause deep ulceration and unsightly cicatrices, is contagious, and is generally spread by sexual intercourse.

3. *Tuberculosis*.—Like syphilis, tuberculosis is the cause of obscure and intractable cutaneous affections. These, however, usually assume the forms of an infiltration tumor, followed by ulceration. If we accept lupus as the type of a mitigated tuberculosis of the skin, we can trace no resemblance either in the history or course of lupus with the case of which I now speak. It is true that papillary outgrowths sometimes occur in connection with lupous lesions, but these proliferations in themselves point to no individual disease. They develop whenever there is morbid hypernutrition of the papillary layer of the integument. There is a form of tuberculosis accompanied by warty growths, known as tuberculosis verrucosa, but it is exceedingly rare, generally attacks the backs of the hands and occurs in those whose duties require them to handle cattle.

4. *Pemphigus*.—A variety termed pemphigus vegetans exhibits papillary excrescences, but these develop upon the basis of bullæ and this form of disease likewise is extremely rare. Here we have had no bullæ.

5. *Sarcoma*.—The tumors of this case certainly bore a considerable resemblance to sarcoma. As a rule, sarcoma advances rapidly, does not cause itching, and seldom manifests any tendency to spontaneous cure. There is, however, a generalized form of this disease, usually developing at or after middle age, beginning as hard edema, upon which nodules subsequently arise and grow slowly; these ultimately become tumors, which are at first hard and smooth but ultimately may ulcerate and assume a fungous aspect. These lesions may progress or retrocede and some may undergo spontaneous cure. The disease may finally involve mucous membranes and cause death. In other cases generalized sarcoma may begin with a solitary growth at some point, the single lesion being followed by other tumors. In this variety of disease the skin prior to ulceration is generally of a livid, brownish or brownish-red color. The tumors of the skin may also coexist with lesions of internal organs or lymphatic glands.

6. *Mycosis fungoides*.—There remains, finally, another rare affection, characterized by fungous tumors and corresponding more closely in lesions and symptoms to the present case than any of those hitherto mentioned. This is the disease known as mycosis fungoides. A synonymous title by which it has been designated, viz., multiple sarcomata, significantly points to the resemblances between the two maladies. Nevertheless, certain clinical distinctions are definitely marked. Mycosis fungoides does not always involve the lymphatic glands, and it never attacks internal organs. It pursues a tardy course, may last for many years and death is at last due to exhaustion, complication or intercurrent disease. Individual patches or tumors may subside without leaving any trace.

Mycosis fungoides usually begins during or after middle age. In a number of cases it has been preceded by some other cutaneous affection, as erythema, erysipelas, eczema, urticaria or furunculosis. The first phase of its development is by no means significant of its nature. Recurrent attacks of erythema, eczema or dermatitis occur for a long time; it may be for years. In the beginning these attacks are amenable to treatment, but with the lapse of time they become more and more intractable. Throughout the course of the disease itching is a prominent characteristic. In accordance with its clinical history mycosis fungoides has been divided into three periods or stages, the eczematiform, the lichenoid and the neoplastic. They all pursue a very tedious course. The patches of seeming eczema are of a dark or light red color. As the case progresses they become more or less raised above the surrounding surface and there may be a little scaling. In the commencement only the superficial layers of the skin are affected, but the deeper parts are at length involved. The affected surface gradually grows rougher and assumes an aspect which bears some resemblance to lichen planus.

Finally, the most distinctive stage, that of tumor formation, arrives. One or more of the lichenoid patches takes on increased development, and bulges forth as a veritable tumor of irregular or hemispheric form, somewhat firm consistence, bright red color and, as a rule, smooth surface. At this stage the tumors were compared by Alibert, who first described the disease, to ripe tomatoes. Subsequently the surface becomes excoriated or ulcerated, rough and fungous. Even at this advanced stage of development fungous tumors may be absorbed and disappear, leaving no trace.

The division into stages is a broad and general one; the scheme of development is marked by many deviations. Lichenoid patches may, as in my case, coexist with numerous and large tumors; the three phases of the disease may be present upon the surface at the same time; the tumors may originate without any preceding manifestation. In a case reported, sheet-like infiltration was observed upon the base of the tongue, palate and in the larynx.

The duration of each stage is indefinite and the entire course of the disease is notably slow. It continues for several or many years. Sooner or later the patient begins to fail in general health. Death at length occurs either from gradual exhaustion, uncontrollable diarrhea or some other complication.

The actual cause of mycosis fungoides is still unknown. It is generally supposed to be of parasitic

origin, but no constant organism has yet been demonstrated.

The treatment has not been very satisfactory. Arsenic, mercury, iodids and other remedies have been employed with variable degrees of success. At the present time we are only able to mitigate the symptoms or lesions of the disease without, probably, exerting much influence upon its course. External applications should be of a sedative and anti-pruritic character.

DISCUSSION.

Dr. DUHRING—Nine cases out of ten are fatal. The diagnosis of the early stage is often very difficult even to an expert. The disease is more common than is generally supposed. The early lesions simulate other diseases very closely, and particularly the erythematous form of eczema. I recall one case which was treated for eczema and within two years the patient died. So it is of great importance to be able to diagnose a case before the fungoid condition makes its appearance, after which it is fatal. I remember a case which was almost clinically like Dr. Shoemaker's, with the exception of the face lesions. The patient was treated with thyroid extract for three or four weeks and the lesions had largely disappeared. The family physician said that the patient had been able to follow his occupation (carpenter) up to two months ago and the main tumors had almost all disappeared. Then the patient suddenly became worse, the tumors increased in size, especially on the neck, axilla and chest, and within one month he sank very rapidly. There was extreme languor and the patient would not leave the bed, after which death occurred in two or three days. There is no hesitation in classing this affection as a distinct disease. I have seen two cases of sarcoma which were generalized and there was no suspicion of their being mycosis fungoides. Both cases died within three months.

Dr. GOTTHEIL—I had a very similar case and all forms of treatment were useless. The pruritus was so obstinate that the patient almost became insane. There were pinkish elevated plaques which itched very much and spread all over the body. The characteristic tumors appeared later. Numbers of previous cases had been diagnosed as eczema, psoriasis, tumors, etc. Every case of an intractable itching cutaneous disease should be suspected as a mycosis fungoides.

Dr. ALLEN—More attention ought to be paid to the premalignant stage. Sometimes the earlier lesions would be like a papular leprosy.

Dr. GILCHRIST—Coley's fluid, which is used in inoperable sarcomata, was tried on a case of mycosis fungoides, fungoid stage (a colored woman), in the Johns Hopkins Hospital, but although some temporary reduction in the size of the tumors had followed, yet no permanent good effects had resulted. I have examined a number of sections taken from three cases of mycosis fungoides and would not diagnose them as sarcomata as some observers have done.

ULERYTHEMA SYCOSIFORME (LUPOID SYCOSIS) WITH REPORT OF TWO CASES.

Presented to the Section on Cutaneous Medicine and Surgery, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY J. ABBOTT CANTRELL, M.D.

Professor of Diseases of the Skin in the Philadelphia Polyclinic and College for Graduates in Medicine, Dermatologist to the Philadelphia Hospital and to the Southern Dispensary.

AND JAY F. SCHAMBERG, M.D.

Instructor on Diseases of the Skin in the Philadelphia Polyclinic and College for Graduates in Medicine, Dermatologist to the Union Mission Hospital.
PHILADELPHIA, PA.

The following report is deemed worthy of presentation on account of the rarity of the disease and the obscurity that has until recently surrounded it. About 1865 the disease was described by Milton under the name "lupoid sycosis." This author says "I have seen in some rare cases (of sycosis) a slow superficial form of ulceration beginning with minute tubercles and attacking the hair follicles causing fall-

ing of the hair and slight though indelible cicatrices, a disorder which seems to me to be nothing more than lupus non-exedens." Unna, in 1889, described a disease which he terms *ulerythema sykosiforme* and reports a case in considerable detail. By *ulerythema* the latter writer means a pathologic process which goes on to the formation of atrophic scars without intermediate suppuration or ulceration; in other words, through the resorption of the cellular infiltrate. We append a full record of the case reported by Unna in order to show the similarity to the case which we describe.

Unna (*Monatshefte f. Prak. Derm.* 1889, ix, 134), records the case of a man 40 years of age, in whom the disease began in 1877 as a small pustule upon the left cheek, which soon developed into a suppurating furuncle. A roundish, reddened, slightly elevated patch about the size of a German thaler gradually formed. This wept and was covered with an accumulation of crusts. The next year there appeared upon the hairy border of the left temple a similar patch covered with crusts. The weeping and crusts continued and the process gradually involved the whole of the left cheek. The hairs of the affected part became loose and could be easily lifted out. Upon extraction whitish nodules were visible upon the hair roots. After the disappearance of the hairs the affected area became pale and there developed smooth flat scar tissue. Two years later a patch developed in the beard of the right side while upon the left the process came to a standstill. Later the patch upon the left side spread over the whole cheek, thence down to the neck. At the same time the moustache became involved upon both sides. Upon the reddened and slightly swollen skin there appeared crops of white vesicles with thick fluid whitish contents. These dried, were scratched open and formed branny crusts which resembled a starch-like dust and the face looked as if it had been powdered. From the beginning the patient shaved to prevent spreading of the affection, but now he rather believes that new points were thereby inoculated.

Present condition. The patient looks robust and has a good healthy color. The hair of the scalp is blond and thick. The beard, which is likewise blond, is only present on the chin and neck. Both cheeks are bald except a small border on the rami of the jaws and there is evident extensive scarring. From a distance even these areas can be distinguished from the normal skin by a bluish red tint, an abnormal smoothness, and an almost satin-like shimmer. On closer examination numerous fine whitish fibers of cicatricial tissue are seen traversing the bluish red background in a sieve-like manner. On the right side of the face the borders of the patch are quite elevated. Here are seen scattered brownish scales penetrated by hairs.

In the middle of the left upper lip there is a patch one-half to one centimeter in diameter in which there is total loss of hair. There is here smooth superficial scarring.

From the middle of the chin a reddish line of small firm papules descends toward the neck and thence turns to the right. On the left side of this line the skin is diffusely reddened and is covered with small round white scales. Near here is a group of five mustard seed sized exfoliation vesicles, three of which are pierced by hairs while the other two are not, but correspond however to follicular openings.

Course.—The course of the disease as well as the above description shows that this affection has nothing to do with ordinary sycosis. Sulphur, resorcin, potassium soaps of all kinds not only did no good but actually inflamed the already cicatricial areas. A constant symptom was the appearance of large numbers of whitish superficial, peri-follicular exfoliation vesicles which rapidly dried and formed crusts. The mercurial preparations alone (mercurial carbolic plaster mull and sublimate in lead water) seemed to do good. On the whole the treatment which produced local anemia was the best. The use of energetic remedies was followed by increased inflammation. At times the parts appeared passive, shortly afterward a high degree of inflammation would ensue after the use of an indifferent remedy. It was evident that there was a deep disease masked by the superficial scarring. Never were any primary purulent vesicles present. The pustules were always due to secondary infection due to pus cocci.

Furthermore the appearance of the pustules did not occur during the acme of inflammation. The patient became improved but not cured. At present there is a very slow amelioration taking place.

Brocq, in his treatise upon diseases of the skin says, "the variety to which I have given the name of 'sycosis lupoides' is observed chiefly in the beard and the morbid process presents a great degree of intensity. The inflammatory lesions are characterized by large peri-follicular pustules, by redness, by thickening of the skin and by the production of crust and scales. There is here a confluence of the neighboring elements. In a word, the affection resembles a non-parasitic sycosis which has arrived at an intense degree of inflammation and infiltration. It differs from it by the constant tendency to a regular centrifugal extension and a total atrophy of the pilo-sebaceous system. All the hairs of the affected region are radically destroyed. There persists after the evolution of the process a central cicatrix more or less hard and thickened, sometimes keloidal. It may however be smooth and soft. Often it presents upon its surface little fibrous bands more or less elevated and irregular. As the affection spreads the center clears up and the pustules, scales and crusts disappear, while on the periphery there is a halo of reddened tissue thickened, inflamed, covered with points of folliculitis, crusts and scales. This is the zone of activity of the affection. The disease thus constantly progresses in the hairy region leaving after it a skin deprived of its glandular and pilous elements, in other words a permanent alopecia.

The diseased areas are rarely multiple, there being seldom more than one or two. They may attain the greatest dimensions unless checked by the most energetic treatment. This affection differs from non-parasitic and parasitic sycosis by its peculiar course and by the characteristic tendency to leave after it a permanent alopecia. One might compare this affection with certain other diseases, until now included under the head of lupus, which also produce irremediable loss of hair; nevertheless, it differs from them by its limitation to hairy regions, by the constant absence of lupoid nodules and the bacillus of Koch. Furthermore by its aspect which is neither that of lupus vulgaris nor lupus erythematosus. French dermatologists have made the diagnosis of "lupus acneique" in the presence of typical cases of this affection. Certain foreign authors have perhaps de-

nominated it lupoid acne but we (Brocq) prefer the name "sycosis lupoides." The most efficacious treatment is that of lupus vulgaris.

Case 1.—L. H., male, age 55 years, native of Philadelphia, a seaman in the United States Navy, now an inmate of the Naval Home, has always enjoyed excellent health with the exception of an attack of pneumonia about twelve years ago. In 1886 the patient suffered from a pustular disease of the beard which lasted two years and then became well. In 1893 he presented himself at the skin dispensary of the Hospital of the University of Pennsylvania with a condition which was diagnosed by Dr. Hartzell, as an ordinary non-parasitic sycosis. The patient stated at the time that he had had an eruption about two years. He remained under treatment for a considerable time, but was later lost sight of. In March 1895 he presented himself to our view at the Philadelphia Polyclinic. At this time the following appearances were noted: The diseased areas involved both cheeks but the condition was more marked upon the right. Upon this side the diseased area was pyriform in

CASE 1.

shape, with the base downward extending from the angle of the jaw to the zygoma, four inches in length. The diameter at the base was two inches, at the stem one inch. The patch presented a pinkish red color, which here and there faded into the surrounding skin, while at other places there was a defined border. Perhaps the most striking peculiarity of the skin over this region was its smooth, glistening, atrophic appearance. Instead of the normal epidermal covering there was a soft shining wrinkled pellicle. Beneath the diffuse redness there was evident throughout the patch, a whitish stippling. The surface gave to the finger passed over it a velvety sensation, but it was evident upon firm pressure that there was increased resistance of the derma beneath. At first sight it appeared as if there were no follicular openings over this area, but upon closer investigation short hairs could be seen piercing the fine epidermis. Some portions of the patch showed complete loss of hair, especially toward the center. Near the periphery there was less hair loss. No follicular suppuration as evidenced by the presence of pustules was noted. The diseased process involved

the inter-follicular region just as much as the hair follicles. Scattered over the patch were perhaps half a dozen vesicles and blebs, varying in size from a pea to a cent. These were very flat, being not more than one-sixteenth of an inch above the level of the skin. The epidermal covering was very thin. Their contents were invariably viscid and transparent. After rupture the vesicles and blebs collapsed and formed brownish crusts which exerted traction upon the surrounding skin throwing it into radiating folds. Some of these crusts subsequently became purulent as a result of accidental infection. Upon their removal there were denuded surfaces which exhibited serous exudation. Here and there was a fine furfuraceous scaling. The entire patch was slightly depressed beneath the surrounding healthy skin. Upon the left side of the face the patch was irregular in shape, about one inch square and one inch above the angle of the jaw and one-half inch internal to the lobule of the ear. There were a few small outlying areas connected with the larger patch by isthmuses. The patch was redder, more sharply defined, less atrophic, and depressed than upon the opposite side of the face. Within two weeks a new patch, about the size of a silver quarter, has made its appearance above the previously described area, but not in any manner connected with it. This patch simply shows hyperemia. As upon the right side there were vesicles, blebs and crusts, remains of former lesions. The course of the disease has been extremely obstinate during the six months that he has been under our observation and there has been absolutely no improvement. On the contrary the patches are actually larger than they were upon his first presentation at the clinic. At certain times there seemed to be an improvement, namely a reduction in the amount of hyperemia and lessened number of vesicles and blebs. This amelioration however seemed to be spontaneous and not the effect of treatment. Crops of vesicles and blebs appeared at intervals of a day or two. They would spring up in a few hours and be attended by such intense itching that the patient would be obliged to rupture them. Sulphur was used, both in solution and as an ointment, without effect. Sedative lotions especially those containing calamine and zinc oxid seemed to give most relief. The patient for a time was placed upon Fowler's solution, 0.25 c.c. thrice daily. Within four or five days a marked aggravation of the condition occurred. There was very rapid spreading of the patch, increased hyperemia, increased bleb formation, and augmentation of the subjective phenomena. Upon the cessation of the drug rapid improvement followed and the face became better than it had been for months.

It will be seen from a comparison of these reports that the disease described is one and the same. The minor differences result probably from the cases having been seen in different stages.

The disease consists essentially of a follicular and peri follicular inflammation which goes on to the destruction of the hair follicles and the formation of atrophic scars. Brocq does not mention the formation of vesicles or blebs but had he kept his cases under observation long enough these might have made their appearance. Unna regards his case as having been from the start an ulerythema; our case had a distinct antecedent history of an ordinary non-parasitic sycosis. There is a general agreement as to the marked rebelliousness of the affection to treatment.

Microscopic examination.—Biopsies were made upon several occasions, small portions of skin being excised from the center of the patch upon the right cheek. The greatest care was necessary to prevent detachment of the thin epidermis. This was so loosely adherent to the corium beneath that a simple vertical incision was sufficient to separate it. In two excisions, the epidermis came off before the biopsy was completed. In the third, by excising a larger piece of skin the epidermis remained adherent to the corium except at both ends. The excised block of skin was hardened in successive strengths of alcohol and imbedded in paraffin. The sections were stained with the Biondi-Ehrlich-Haidenbain stain, hematoxylin and eosin, and by Gram's method.

The stratum corneum and stratum lucidum are absent. The stratum granulosum is present and well marked. The rete mucosum presents no pathologic changes. It is detached from the papillary layer of the corium at both ends of the section; in the center it remained adherent; the point of adhesion corresponds to the mouth of a hair follicle. On examining the specimen under low power there is at once apparent an intense sharply defined cell infiltration. Innumerable nests of varying sizes and shapes filled with deeply stained cells are scattered throughout the corium. Their walls consist of fibers of connective tissue. This cell infiltration is most marked around the hair follicles, of which there are several in the section; furthermore, the infiltration is densest near the mouths

of the follicles. The papillary layer of the corium shows great overgrowth of connective tissue, between the fibers of which are scattered cells. The papillary blood vessels are obscured from view by this fibrous tissue. These nests of cells extend from the sub-papillary layer down to the deepest portions of the corium. In certain places fibrous connective tissue seems to have replaced previously existing hair follicles and sebaceous glands. The sections, in all, show but three hair follicles and no sebaceous glands. As the piece of excised skin was quite large and taken from the center of the bearded region it is evident that there is considerable pilo-sebaceous atrophy. The sweat glands appear normal. Numerous sudoriferous ducts are seen coursing through the corium and are, for the greater part, normal although a few present some cell infiltration.

The cell infiltrate is composed chiefly of leucocytes although there are also present cells derived from the connective tissue corpuscles. The round cells however are in great preponderance. Giant cells are absent. The examination for tubercle bacilli is entirely negative.

While this affection simulates lupus vulgaris both clinically and pathologically it is evident that it is not identical with that

CASE 3.

disease. The cicatricial appearance, the extreme rebelliousness to treatment and the circumscribed cell infiltration are certainly suggestive of lupus; on the other hand the absence of lupus nodules and ulceration clinically and the absence of giant cells and tubercle bacilli in the microscopic section prove it to be something else. We agree with Unna in regarding this disease as a distinct entity and accept his name "*ulerythema sycosiforme*" as the best one from our present knowledge of the disease.

Two years later this case shows the following appearances: The patch on the right side was markedly white and atrophic, the border was slightly infiltrated and raised, there was absence of vesicles and blebs. The entire process seemed to be inactive.

Upon the left side there was peripheral spreading of the patch, the border being marked by red inflammatory pustules. The patient stated that for a period of two months the disease seemed to have been cured.

Case 2.—J. Q., aged 35 years, laborer, six years ago noticed pustules in the beard of the left cheek. He states that since then the affection has been gradually growing worse.

Present condition.—The diseased area upon the left side is irregularly oval shaped, being about three inches by one inch in diameter and extending from the zygoma to a point one inch below the angle of the jaw. The epidermis of this region is smooth, shining and atrophic; by pressure it is thrown into radiating folds. The patch is whitish but presenting a mottled reddish appearance due to a superficial telangiectasis. The aural border of the patch is considerably raised above the level of the skin and exhibits, to the touch, marked infiltration, keloidal in character. The hair follicles and the mouths of the sebaceous glands are entirely absent over this area.

Upon the right side there was a triangular patch one and a half inches by three-quarters of an inch. The border is markedly infiltrated as upon the opposite side. There is atrophy of the hair follicles but the atrophic appearance of the skin is not as marked as on the left side. Below this patch are several follicular pustules and the disease seemed to be spreading in this direction. Acne lesions were present upon other portions of the face.

There were no vesicles or blebs present.

DISCUSSION.

Dr. ALLEN—There exists a disease, call it lupoid sycosis or ulerythema sycosis, which differs from lupus erythematosus. I am surprised to hear that this disease resembles lupus vulgaris, but to me, the lesions appear more like lupus erythematosus than lupus vulgaris. Lupoid sycosis is in my opinion a distinct disease.

Dr. DUHRING—The experience with this disease has been so limited that we have to view the clinical appearances with much care. I have seen a few cases, some of them ill-defined and others well marked. Both cases I thought were characteristic examples of this disease. Lupoid sycosis was a disease which presented many clinical pictures; some writers describing it as resembling lupus vulgaris, others as lupus erythematosus and others as acne. When I looked at the first case I thought it presented features more like lupus vulgaris than lupus erythematosus; so it might be mistaken for the former disease. The second case resembled more an acne and resembled a case which had been under my observation for a year and the man was getting well under mild treatment (sulphur ointment). The hairs were returning, which showed that the hair follicles had not been destroyed. Others who had seen the case were surprised at the return of the hair. I had been inclined to class it with the sycosis but now altered my opinion. The prognosis in this disease was not so unfavorable as others had supposed, since in one case I have seen the hair return. In the second case the idea of parasitism had not occurred to me except perhaps in connection with the lesions on the neck.

Dr. FORDYCE—Until we know more about the pathology of lupus erythematosus it will be difficult to classify this disease. The case is very like lupus erythematosus because of the sharply defined edge of the lesion. The microscopic picture also resembles closely the same disease. The presence of nests of small cells and the absence of giant cells would cause me to group it under lupus erythematosus rather than sycosiform.

Dr. SCHAMBERG—These cases present different types of the disease and they agree in many respects with Dr. Duhring's case. In the latter the skin was soft and there was no inter-follicular scarring. All the cases of this disease are preceded by sycosis and one case was more like lupus erythematosus, but there had been no scales, whereas in the other patient blebs had made their appearance at one time, a lesion which never appears in lupus erythematosus. Blebs did not occur in Duhring's case; I think that pressure of the collection of cells on the neighboring nerves might have caused the bleb formation. I have never seen such deep infiltration of cells, in the corium, in lupus erythematosus.

THE SYMPTOMS AND NATURE OF ERYTHEMA MULTIFORME.

Presented to the Section on Cutaneous Medicine and Surgery at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY LOUIS A. DUHRING, M.D.

PHILADELPHIA, PA.

By the term erythema multiforme I understand a disease characterized by certain tolerably well-defined erythematous lesions upon the skin, which undergo a variable evolution with a tendency to run an acute course and to recover spontaneously. The lesions are chiefly erythematous in type and are superficial, their

seat being in the corium, especially in the papillary layer. They are not hyperemic but are distinctly exudative in character. They consist of macules, maculo-papules, papules, papulo-vesicles, vesicles and blebs. They manifest a disposition for one form to pass into another, thus frequently, but not always, constituting a multiform eruption, hence the name erythema multiforme, originally proposed for the disease by F. Hebra. While therefore a notable variety of lesions frequently, but not always, characterize the disease, it must not be supposed that every exudative erythema is necessarily an erythema multiforme. There are certain polymorphous erythemata which are to be classed as erythema exudativum which are not instances of erythema multiforme, as for example erythema scarlatinoides. In the several cutaneous manifestations of erythema multiforme there are characters common to all the varieties of lesions, as regards their form, shape, outline, their occurrence together or in proximity, color, evolution and involution, which stamp them as being merely different inflammatory expressions of one process. They constitute a group of peculiar inflammations, for the most part erythematous lesions, to which we give the name erythema multiforme. They may be distinctly marked in their general features, constituting easily recognizable dermatoses, or only faintly pronounced, so that possibly the diagnosis can be made only by observing the case for a few days and noting the evolution of the process. In my own field of observation many more of the latter than the former cases present themselves. Well-defined cases, such as are usually selected by authors to illustrate atlases of the diseases of the skin, are comparatively rare in Philadelphia. There occur, as I view the subject, a number of cases of acute, ill-defined erythematous diseases which are difficult to classify because they show so little that is distinctive, and yet if they are followed from the beginning to the end of the cutaneous manifestations, will usually give evidence that they are actually faint expressions of erythema multiforme. In defining disease authors, I think, are inclined to adhere too closely to recognized types of diseases and do not allow sufficiently for variations. Having only defined types in mind the clinician may fail to recognize the disease before him because it falls short of the accepted sharp definition.

As already intimated the predominant idea the world over of erythema multiforme comprises an acute disease, running usually a course extending from one to three weeks and which may relapse or recur at shorter or longer intervals. The lesions, whether in the form of macules, papules, vesicles or blebs, are inclined to be sharply circumscribed, and especially in the case of macules, to be marginate. The color is a bright, vivid or deep red, often a raspberry red. The maculo-papules, papules and papulo-vesicles are three forms frequently occurring together or in sequence, are peculiar in that they almost invariably undergo in the course of their evolution central superficial necrosis. As they grow and extend in size they break down in the center, forming a slight or marked depression and a crust, the latter often being insignificant. This is one of the characteristic features of the maculo-papular, papular and vesico-papular varieties of the disease. It is not only a clinical but also a histo-pathologic feature. Where the process inclines to manifest itself on the skin as a broad erythematous lesion, occu-

pying a small area, or, it may be, the greater part of the general surface, margination in the form of arcs and segments of circles is common. This is often, but by no means always, due to the confluence of several lesions. The mere fact of confluence will not give rise to these peculiar forms, other factors, in connection especially with nerve influence, being, I believe, accountable for it. The angio-neurotic or vasomotor nature of the disease is exemplified not only in this feature but in many other ways. But this observation does not inform us of the intimate nature or the cause of the manifestation. I may here refer to features which every clinician has observed, but what authors fail to dwell upon sufficiently, that the nervous system influences the cutaneous manifestations of the disease in a remarkable manner. There exists in connection with most of the somewhat diverse lesions a notable tendency to spread on the periphery while healing or disappearing in the center. It presents many of the features of herpetism. The process in its course is much like that of *tinea circinata* due to the presence of a fungus. It has often occurred to me to query why the natural lesion and the evolution of these two processes, due to entirely different causes, so far as we are able to determine this point, should be so much alike in many particulars. One is due to some unknown cause acting from within, the other from a well-known cause acting from without, yet the lesions and their evolution possess features which link them from a clinical standpoint. So much so is this the case that until within the last thirty or forty years these diseases were confounded by the most experienced dermatologists. The question of interest is to determine what part, if any, the peripheral nerves or the central nervous system play in the production of the circinate lesions of *tinea circinata*.

Having decided in outline the general character of the local manifestations, it may be inquired what, if any, are the constitutional or general symptoms. Do the latter always occur and thus form a part of the disease? In approaching this subject I desire to lay special stress on the observation that in the descriptions of erythema multiforme in text books, very little is said about the general symptoms. They are, I think, oftener present than is usually conceded. If this be true it would show that they are almost as much a part of the process as the cutaneous manifestations. This I believe to be the case in many instances. The general symptoms, however, are more variable in form than the manifestations upon the skin, and for this reason probably are overlooked or are not taken into account in viewing the entire process. In mild cases, of which a goodly number have come under my observation, they may be trivial. I will refer first to the milder symptoms. They naturally vary somewhat with the age of the patient, but in adolescents or young adults consist of malaise, lassitude, aching in the limbs and trunk or joints, loss of appetite, furred tongue, constipation, fever in a variable degree, often slight, parched lips and the like. It may be observed that such symptoms are in no way peculiar, being seen in a multitude of acute diseases. This is true, but they nevertheless constitute in many instances, a part of a process of which the cutaneous symptoms are the most striking. The amount of the cutaneous disturbance, however, by no means always indicates the gravity of an entire disease. Thus, by way of example, in dermatitis exfoliativa the cutaneous manifestations may be severe and the

general symptoms slight, while on the other hand in some cases of the eruptive febrile diseases, as measles, the cutaneous are slight and the general symptoms pronounced. If we note the general symptoms in a sharp attack there may exist distinct rheumatoid symptoms, including articular stiffness, swelling or pain, localized or fugitive, together with all the symptoms enumerated as liable to be present in the milder forms of the disease. These and other, sometimes graver, symptoms may make their advent suddenly or gradually before or with the appearance of the eruption. I would interpret them, as I would the eruption itself, as being in many instances due to an infection, similar in nature to that which occurs in certain other erythematous efflorescences upon the skin, as for example, rubella and pityriasis rosea. I believe, then, that what we call erythema multiforme is in reality a general disease, in many instances, of an infectious nature. Of the precise nature of the infection we know little or nothing. I venture the opinion, however, that the cause is probably allied in nature to those which give rise to influenza and similar diseases, and probably to those which occasion some cases of so-called pityriasis rosea. I say advisedly some cases because I think it will be found that several diseases have been included under the heading pityriasis rosea, some acute, others chronic in course.

There is another group of cases, much smaller than those mentioned, that are well known, and which generally pursue a chronic course. The symptoms are more general and graver in character than in erythema multiforme, the lesions being hemorrhagic. The general symptoms are similar or like those I have briefly outlined as occurring in some cases of severe erythema multiforme, but they are more pronounced, and in addition hemorrhages occur, slight or severe, which may relapse or recur in the intestinal tract or elsewhere. The cutaneous lesions are hemorrhagic and not erythematous; that is to say, that take on a hemorrhagic character either in the beginning or soon after, the erythematous character being for the most part or wholly wanting. These cases belong to the hemorrhages of the skin rather than to the erythematata. They possess much in common with infectious purpura, and I think should be regarded as examples of that disease. I make this observation because some writers of late have been disposed to consider them as erythema multiforme. Thus, we note that Osler has recently reported an interesting series of these cases, designating them erythema multiforme. The latter title, in my opinion, is inapplicable to these cases, which if they are investigated will be found to possess the symptoms of purpura rheumatica much more definitely than of erythema. If we group these purpuric cases with the erythematata it will become necessary to change the definition of erythema, which we are by no means prepared to do. I grant that the causes which may give rise to some cases of erythema multiforme may in like manner be concerned in the production of some forms of purpura, and I am of opinion that such is sometimes the case. But this fact does not make them one and the same disease. One cause may give rise to several diseases, in one case involving internal organs, in another instance the integument. The points to which I have directed special attention are the following:

1. That erythema multiforme is a disease of the skin, having a clearly outlined definition as regards the cutaneous lesions.

2. That general or systemic symptoms are often obviously recognizable, and occasionally are severe.

3. That we should distinguish between erythema multiforme and other forms of exudative erythema, not every exudative erythema being an erythema multiforme.

4. The term erythema multiforme should be confined in its employment to characteristic inflammatory manifestations, especially of the superficial strata of the skin, and that where pronounced hemorrhagic lesions occur in the integument, as well as elsewhere, the disease should be viewed as purpura.

5. Erythema multiforme is probably not infrequently an infectious disease, both the general and local symptoms pointing to this conclusion.

DISCUSSION.

Dr. BAUM—I have seen both varieties of erythema multiforme on the same patient, *i. e.*, the erythematous variety on the upper extremities and the hemorrhagic lesions on the legs. I think the disease due to a vasomotor disturbance. I recall a case of this disease in which there were present alternating bullous and hemorrhagic lesions. A relapse had occurred after the death of a sister and it presented the large bullous variety in the hands. I think there were lesions also in the bowels, because there was marked irritability there.

Dr. BULKLEY—I consider it an infectious disease and due to an auto-intoxication. I have seen many cases of this disease in recently landed immigrants. I advise the administration of Startin's mixture and a calomel purge. The rheumatic element occurs sometimes and I regard it as another symptom.

Dr. HARTZELL—All the cases classed under this disease do not belong there. Erythema multiforme exhibits special features of an infectious disease. There are joint affections which are rheumatoid in character, but it is not rheumatism. I do not think the course of the disease is at all influenced by treatment. A number of cases are due to various poisons, *e. g.*, drugs, but the lesions should not be classed as erythema multiforme.

Dr. POLLITZER—The cutaneous lesions are only symptoms of a general disease and the affection is due to some disturbance of the blood vessels. Pathologically there is an erythema accompanied by an exudate and the hemorrhagic form is only one of degree. I do not think it correct to classify the purpura which sometimes follows the ingestion of quinin, with the thrombosis of endocarditis.

Dr. COOK—I think erythema multiforme a group of diseases due to neurotic influences.

Dr. GILCHRIST—I consider the cutaneous lesions are probably the expression of a general affection. I have examined numbers of microscopic sections taken from four or five cases of the erythematous variety of this disease and also from one case of the bullous form. The results of my observations seemed to point to the fact that the cutaneous lesions were brought about by some toxin or some micro-organisms which could not be demonstrated, forming or developing directly beneath the epidermis. The polynuclear leucocytes wandered out into this region and appeared, in the vesicular variety, to become disintegrated or killed as soon as they had wandered out. This condition seemed to point to the fact that the poison was a powerful one. This remarkable microscopic picture could not be explained by any neurotic influences, nor by any alteration in the vessels. The bullous and hemorrhagic varieties of the disease were only one of degree.

With reference to immigrant dermatitis, a good deal of experience was had with this affection in Baltimore, since it was a considerable port of entry for immigrants. I would not class this group with erythema multiforme but would consider it as a separate affection. In the treatment of erythema multiforme I have found sodium salicylate very efficacious.

Dr. DUNNING—Most of the speakers agree with me that there is more in this disease than appears on the surface. I consider Hebra's definition, which was given thirty-five years ago, just as applicable today and could not be improved upon. Hebra, however, did not touch upon the constitutional symptoms. Erythema multiforme is not hemorrhagic. Although the causes are identical, yet all the varieties are not infectious. Immigrant dermatitis I would call erythema exudativum. The cases of erythema multiforme I have seen in Philadelphia are milder than those seen in New York, London, etc.

ON VARIOUS FORMS OF CUTANEOUS TUBERCULOSIS.

Presented to the Section on Cutaneous Medicine and Surgery, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY A. RAVOGLI, M.D.

CINCINNATI, OHIO.

The affections of the skin produced by tuberculosis have shown such a variety of form that they offer nearly the same interest as those arising from syphilis. On account of the complex construction of the skin the tubercular lesions must present a different appearance according to the organs and tissues of the skin involved. When the glands of the skin are affected we see lichen scrofulosorum or folliculitis; when the lymphatics are affected, the disease manifests itself in the form of tubercular gumma, and as verrucous cutaneous tuberculosis, or lupus, when the papillary layer or the derma is invaded.

Figure 1.

The cause of these eruptions is the tubercle bacillus, which is found in the structure of the skin. We have, however, other cutaneous eruptions where no tubercle bacilli are present, and they are the result of its toxic products. The toxic power of the tox-albumins has been already demonstrated, and it gives the explanation of those forms of lupus erythematosus and of lupus pernio of Hutelinson. In these cases the tubercle bacillus may be in the internal organs far from the skin or in the mucous membranes near the affected skin, and the toxins are the cause of the eruption which is only symptomatic and persistent on account of the persistency of its cause.

The most superficial form of tubercular erythema is considered a serious symptom for the future of the patient. Erythematous eruptions in form of roseola

remaining from twenty to thirty days have been observed by Bayet and Schlangreiff, in individuals affected with acute pulmonary tuberculosis. Last year I attended a lady with a superficial form of lupus erythematosus of the face and hands, suffering with advanced pulmonary tuberculosis. The eruption on the face appeared two months after the pulmonary symptoms became manifest remaining for over one year and when the pulmonary symptoms increased in severity, the eruption had nearly disappeared.

Those forms of cutaneous tuberculosis, in which the tubercle bacillus and the tubercular process is present in the skin, are the subject of this paper. In many of these cases we find the individual in good general health, in spite of the cutaneous ulcerations. Some of these forms are the result of auto-inoculation, the tubercle bacilli from the same person inoculating the skin, others are the result of outside inoculation as in verruca necrogenica.

H. Hallopeau¹ calls these forms *tuberculoses cutanées bacillaires* in order to indicate that they are the

The examination of the sputa revealed a large number of tubercle bacilli. The eruption began on the extensor surface of the right arm near the wrist joint, with an intense itching and an erythematous patch which became somewhat swollen and was soon covered with small pustules, forming dirty brown crusts. While the pustules were spreading superficially in the middle, ulcerations formed which gradually gave place to vegetating granulations, showing the verrucous appearance. Almost contemporaneously patches of the same nature affected the lips, spread upon the nose, cheeks and forehead, scalp and both sides of the neck. On account of the itching sensation she often rubbed the spots and the other hand was inoculated on the dorsal surface of the third finger in the form of a large eruptive spot with the same characteristics as the spots on the face. From cut one can easily see the three zones described in the typical patches; the outer zone erythematous, slightly raised above the level of the normal skin, the middle zone, which consists of a dusky livid infiltration with scattered ulcerations, and small abscesses, somewhat

Figure 2 a.

Figure 2 b.

direct result of the presence of the tubercle bacillus in the skin. In these cases we have the alterations in the papillary layer with accompanying lesions of the epidermis and often also of the derma. The lesions of the papillary layer take on a vegetating form, for which reason they were called by Riehl and Paltauf, *tuberculosis verrucosa*, or *tuberculosis papillomatense* by Besnier, Deboue and Brissaud.

The illustrations are of three cases of cutaneous tuberculosis of this kind, where the infection came directly from the same individual, and in each the affection showed a different course and appearance.

Figure 1 shows an extensive tubercular eruption in a lady 52 years old, suffering with pulmonary tuberculosis for over three years, accompanied with profuse expectoration. The eruption has now completely disappeared and only superficial scars show the spots formerly occupied by the eruptive plaques.

raised above the former; the inner zone shows fissures and sprouting up from them are small warty projections making this zone somewhat higher than the others.

I was not allowed to make microscopic examinations of the case, but the attending physician asserted that he found tubercle bacilli in the secretion of the ulceration. The most remarkable feature in this case was the relatively acute course and the recovery. The eruption lasted from three to four months, recovering gradually like any other superficial ulceration, leaving a red parchment-like scar. The lady has also improved considerably in her general health.

Figure 2 is another case of tuberculosis verrucosa cutis, which lasted over four years in spite of strong and constant treatment. At present the ulcerations have nearly all healed. The patient is a man of strong physique, molder by trade, has always enjoyed good health, never had syphilis. Five years ago he had an abscess on the internal region of the left leg

¹ Sur le rapports de la tuberculose avec les maladies de la peau, autres que le Lupus Vulgaire, Third International Congress of Dermatology, 1896.

with caries of the tibia. In the cut an irregular scar in this region shows it plainly, and at this point was the beginning of the cutaneous ulceration. It spread from the edges of the wound and gradually extended, covering the whole extent of the limb, to the dorsal surface of the foot. At the same time another abscess of the same nature, with caries of the bone affected the right leg. Under surgical treatment the bone healed, the surface was covered with granulations, but no healthy scar could be obtained. The ulceration spread with exuberant vegetations, encircling the whole calf of the leg, reaching the opposite side in the malleolar and tarsian region. The vegetations were in the form of a mass elevated above the level of the normal skin, easily bleeding in some places, covered with crusts, in others with thick epidermic masses. The detritus was often examined for the tubercle bacillus, but it was never found. In a few sections the epidermis was much thicker, red and of verrucous appearance, the papillæ greatly enlarged, with an enormous infiltration of small round cells, in some places arranged in foci, resembling the tissues affected with tuberculous inflammation. In some, few giant cells could be found surrounded by numerous nuclei of a tubercular character.

In this year after a tonic internal treatment the patient has gained considerably in flesh. The patches have been cauterized with Vienna paste, in other places have been curetted, and gradually with the application of a resorcin and creosote salve the ulcerated surface began to appear more healthy and had nearly all healed, leaving scars and an atrophic condition of the affected regions.

Bacillar infection may be carried from the lymphatic glands to the skin as we often see in the scrofuloderma. The same infection can at times be spread from the inguinal glands to the skin and surrounding tissues in the form of phagedenic bubo. Figure 3 shows a young colored man with an enormous ulceration of the right groin spreading down to the internal region of the thigh, on the penis and on the scrotum, and another beginning on the other groin.

He is 20 years old; his father is living and in good health; his mother died of consumption. He has been affected with scrofula, and the condition of the cervical glands, swollen and covered with scars, attests it. He was admitted to the hospital for inguinal bubo. He stated that nearly eight weeks before entering the institution he noticed a small ulceration at the end of prepuce. A few days after there appeared a swelling of the left groin. The skin soon became tense and painful, broke down and discharged a foul sanguinolent and purulent fluid. He stated that the sore on the prepuce appeared two months after the last intercourse. When he was admitted Nov. 7, 1896, he appeared to be well developed and nourished, only his neck showing many scars of old tubercular glands. Both lungs gave mucous râles at the apex in prolonged expiration, no dulness. The body was free from eruption, no sore throat, no alopecia. The right inguinal region showed a swelling of about the size of the fist, two small openings gave issue to some blood and pus. The base of the swelling was hard for some distance. Glands of left groin were also enlarged. There was a small, hard, superficial ulceration on the free end of the prepuce. Under chloroform the right groin was opened, thoroughly curetted and packed with iodoform gauze. Instead

of obtaining cicatrization, the whole surface began to show a large ulcerated surface, with fungous growths affecting the inguinal region to the internal region of the thigh, the scrotum riddled with sinuses, the skin of the penis showed hard lymphatic vessels like small gummæ, which gradually formed abscesses and ulcerations with the same fungous appearance. The left inguinal glands were hardened and formed a large mass with points of suppuration beneath.

February 1 the patient was again placed under the anesthetic; the sinuses were opened, the glands removed, the granulations thoroughly curetted and the whole surface was cauterized with the thermo-cautery. Succeeding dressings were made with acetanilid. Although no symptoms of constitutional syphilis had so far appeared, yet liquor Van Swieten had been administered, together with tonics and reconstituents. Mercurial plaster had been used on the ulcerations without result. In order to observe the reaction to tuberculin, injections were given of from 1 to 5 mgr., and at every injection he had fever ranging from 101 to 103 degrees F. When I went out of service the ulceration was somewhat healed, the granulations appeared healthier and the patient was able to go about. Symptoms of pulmonary tuberculosis were more apparent.

I have referred to this case as an example of mixed infection, and from many cases of phagedenic ulcers I must come to the conclusion that tuberculosis of the glands and lymphatics is often mixed with the virus of chancreoid or syphilitic lesions, producing the dreaded destructions of phagedenism.

This boy was affected with tubercular glands, and when the glands broke down on account of the other infection, tubercle bacilli came in contact with the ulcerated surface, causing a tubercular ulcer in place of the bubo. The gumulous tuberculosis is in many instances the cause of the cutaneous tubercular ulcers; this is a kind of intermediary between the deep-seated tuberculosis and the superficial of the skin. In all tubercular forms we must see a mixed infection, as the cocci of the pus appears in every tubercular process as secondary elements, so that we find in the middle a cheesy, degenerated point with a purulent softening, as referred to by Leistikow.² In cases of phagedena we may have not only the staphylococcus pyogenes and the tubercle bacillus, but also the syphilitic virus or the micro-organism proper to chancreoid, which are the commencing agents of the ulceration.

In our case it is rather difficult to establish with certainty whether the ulcer which started from the prepuce was a chancreoid or a syphilitic one. The patient after six months has not yet shown any syphilitic symptoms, with the exception of the phagedenic bubo. It is also hard to believe it a chancreoid, when the patient asserts that the ulcer appeared two months after the last intercourse. It seems to me that an accidental sore of some nature, has started the inflammatory process in the lymphatic vessels of the penis and inguinal glands which, affected already with tubercular process, broke down, causing extensive abscesses, and the tubercle bacilli from the tubercular glands have infected the surrounding tissues, causing a cutaneous and subcutaneous tubercular gumulous ulceration. The ulcers of the dorsum penis and scrotum are due to tubercular lymphangitis, as we found the affection to start directly from the lymphatic vascular trunks. They appeared at first hard

² Über Skrofuloderma, Mon. Hefte für Pract. Dermatol., ix Bd. 1889.

like stems under the pressure of the finger, then they became larger, of dusky color, breaking down into a quantity of purulent and sanguinolent fluid and a great discharge of lymph. In this case two conditions could have been the cause of the process. Either the ulcer itself was of tubercular origin and infected the lymphatics, or the lymphatics were already infected with tubercle bacilli, as were the inguinal glands, and therefore the staphylococci started the inflammatory process around the already infiltrated tubercular tissues producing tubercular ulcerations with papillary growths.

I referred to these three cases of tuberculosis verrucosa cutis on account of their peculiar origin. The first was the result of the inoculation of the tubercle bacilli from the sputa; the second was produced by the tubercle bacillus from the diseased bone; the

ing to the distinction proposed by Maurice Vallas.³ In these cases we do not find any outside inoculation; they are bacillary in their nature like lupus, and are primary, showing no trace of their origin. They could be ranged with Leloir⁴ among the atypic varieties of lupus.

Figure 4 is a good specimen of this variety of cutaneous tuberculosis. It is of a man 30 years old, of good physique, blond, lumber-yard hand by occupation. No history of tuberculosis nor cancer exists in his family. He never had syphilis, has always enjoyed good health. Dec. 29, 1896, he came to the hospital for ulcerations of the skin. The eruptions had begun fifteen months previously, at first in the form of a little indurated red patch over the crest of the left ilium extending internally. It gradually spread and began to break down in the center, form-

Figure 3.

third from the bacilli contained in the tubercular glands.

Each one has some important features. The first in which the papillary layer and the epidermis only was superficially affected, healed in about four or five months, leaving superficial scars. The second which affected the derma deeply formed thick vegetating papillae which lasted nearly four years, stubborn and persistent in spite of the surgical means employed. The third, a type of mixed infection affecting the skin in its deepest layers and the fascia, with vegetating and papillomatous appearance, equally resisted the cauterization and the curetting. There is no doubt that the layers of the skin affected have much to do with the more or less persistent character of these affections.

I now call your attention to two cases, which I classify among the the scrofulo-tuberculosis, accord-

Figure 4.

ing an irregular ulcer, tender and slightly painful. When the ulcerated patch had attained the size of a silver dollar, healing began at the center, leaving an irregular thick and superficial scar. The peripheral ulcerations continued spreading and after assuming the size of the palm of the hand, stopped and after some months healed. Other patches of the same character after an interval of two months appeared, one on the right leg near the knee, one on the abdominal wall to the right of the umbilicus, one in the right axilla and shoulder, and one on the right side of the mouth, involving both lips. The eruption consisted of nodules deeply seated in the derma and coalescent at the periphery of a thick cicatrix, resembling the lupus scars. Some of these nodules were

³ Les ulcères tuberculeux de la peau, Thèse de Lyon, 1887.

⁴ Ann. de Dermat., 1888.

already ulcerated and covered with thick brown crusts, and some with thick epidermic scales.

Under the microscope the corium appears affected with round foci infiltrated with small cells grouped together. The same cells are infiltrating the connective tissue, and the fascicles appear in a reticular manner separated by the cellular infiltration. Small blood vessels appear enlarged and some are plugged with infiltration, showing a kind of endo-arteritis. In some places the papillae have been destroyed by the infiltrating elements, and where they remain appear enlarged and hypertrophic.

Tubercle bacilli were not found. No doubt this was a tubercular form of cutaneous disease, which had a great resemblance to lupus, and which we can refer to as an atypical variety of lupus.

The treatment consisted in tuberculin injections of from 1 to 2 mgr. every other day. The first injections were followed by fever and local reaction. The temperature rose three hours after the injection to 102 F., with symptoms of general malaise, pain in the spinal region, and sometimes vomiting. On the local spots, the reaction was exceedingly marked, an intense vivid purplish color showed all over the patches and nodules, and the ulcerated spots appeared of dark brown color, as after cauterization. After the third injection the temperature rose only to 99 with very little general disturbance, but the local reaction was always marked. Locally a dressing of sterilized vaselin was used. The crusts were soon removed; the ulcers began to be covered with good granulations, and on January 9, the ulcerations having completely healed, the patient was discharged.

Figure 5 shows another superficial tubercular skin eruption of ulcerative nature, which can be referred to the same class of tuberculosis lupoides. The patient was admitted to the hospital Jan. 11, 1897, for a diffuse ulceration on the left thigh, coursing nearly the entire gluteal region and abdominal wall. Another patch of the same nature is in the left mammary region. He was 44 years old, of poor physique, had suffered a long time with pleuro-pneumonia, no history of syphilis can be found. The present eruption began three years ago as a small hard patch, somewhat elevated above the level of the normal skin which soon broke down, causing an ulceration. This enlarged in a serpiginous way, healing slowly in the center and ulcerating at the edges, until in nearly three years it had taken on the proportions referred to. The ulcerations after healing left very superficial scars, depressed in the center and atrophic, which gradually became very white.

The examination of the chest did not reveal marked dulness nor râles.

The affection had been treated previously as a syphilitic one with iodid of potassium and local application of mercurial plaster, with little results.

As soon as he entered the hospital he had tuberculin injected from 1 to 3 milligram. The fever was not marked, but the local reaction was very striking. The whole affected surface became a purplish red, and the ulcerated places appeared as though they had been cauterized.

In this case also, the whole treatment consisted in tuberculin injections alternate days. Elixir of iron, quinin and strychnia internally, and locally a simple dressing with sterilized vaselin.

Under the tuberculin the progress was so rapid that March 18 he left the hospital entirely recovered.

This case was somewhat different from the preceding. The infiltration was much more diffused and superficial, resembling more lupus erythematosus than lupus vulgaris, while the other was more like a case of lupus vulgaris.

The marked reaction to the tuberculin injections is an important point for the diagnosis of the tuberculosis of the skin, and the result obtained under its use is a guarantee that the affection could not be from any other cause.

Prof. V. Bergmann, at the meeting of Freien Vereinigung der Chirurgen in Berlin, November, 1890, referred to a case of tubercular ulceration of the lower jaw and palate, which healed entirely after a few injections of tuberculin 0.1, 0.2. He noticed slight general but very marked local reaction on the first day.

After the tuberculin injection the tubercular nodules appeared much smaller and the ulcerations as if they had been cauterized. Dr. C. Schimmelbusch⁵ stated that he could not find true necrosis in the tubercles of the skin after tuberculin injections, but the tissues showed only an inflammation and an exudation process, causing a sloughing of the ulceration.

The important feature in these last cases is the curative effect of the tuberculin: only simple vaselin dressings were applied to the local ulcerations.

I have referred to these cases, which lately came under my treatment, on account of the interest which they offer to the dermatologist. The first three cases, tuberculosis verrucosa cutis, are of scientific importance on account of the source of infection, and the course and extension of the lesions. Suppuration is the principal cause of spreading of this tuberculosis and miliary foci are formed, so that the pyogenic cocci cause the extending of these eruptions. In these forms tubercle bacilli are difficult to find and Riehl and Paltauf believed the cause of this affection to be due mostly to a mixture of the infectious germs. Nearly all cutaneous tuberculosis end with ulceration; in some, however, the ulceration is a most remarkable phenomenon, showing a tendency to proliferation.

The two last cases have more resemblance to lupus, and especially the last case can be compared with lupus tuberculosis superficialis, as described by W. Dubrulle at the Society of Medicine and Surgery of Bordeaux. In these cases we find small superficial tubercular gummata, which after ulcerating have a tendency to recovery, leaving a superficial scar.

In the tuberculosis of the skin, with the exception of the tubercular ulcers, which are developed near the natural orifices in advanced consumptive patients, and which have a destructive nature, the other mentioned forms usually recover. It seems that the tubercle bacillus in the skin is somewhat modified, has not much tendency to multiply, and is not easily inoculable. The derma does not offer to this bacillus a fertile ground and its infectious properties remain limited to the skin, without showing general infectious phenomena. At times the infectious power of this germ, when encapsuled in the tissues, may remain latent for years, ready to break out at any time in the form of lupus from old scars.

In all our cases we have seen recovery of the cutaneous tubercular form. In the forms of tuberculosis verrucosa, by means of curetting, the cautery and various dressings we have obtained recovery. In the

⁵ Mikroskopische Befunde der Tuberculose der Haut, und der Sichtbaren Schleimhäute nach Anwendung der Kochschen Mittels. Deutsch. Med. Woch. 1896.

two other cases. the tuberculin injections produced beneficial influence on the tubercular cutaneous forms. No other dressing was used than vaselin, and yet after several injections the ulcerations healed promptly.

I will say in conclusion, that cutaneous tuberculosis occurs not very rarely; that it is not always accompanied with general tubercular infection; that it has a tendency to recovery; that it may yield to local as well as to general treatment; that tuberculin injections for some ulcerative forms have a beneficial influence.

THREE CASES OF TUBERCULOSIS CUTIS VERRUCOSA.

Presented in the Section on Cutaneous Medicine and Surgery, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY M. B. HARTZELL, M.D.

INSTRUCTOR IN DERMATOLOGY, UNIVERSITY OF PENNSYLVANIA.
PHILADELPHIA, PA.

Although that form of tuberculosis of the skin first described by Riehl and Paltauf, under the name of tuberculosis cutis verrucosa can no longer be regarded as a rare affection, and usually presents such well-marked and special features that its diagnosis is ordinarily made without any difficulty, I have thought that it might be of interest to report the three cases the subject of this paper, since each of them presents features, clinical and histologic, which are uncommon. The first case reported, presented in its early stages a form of cutaneous tuberculosis to which attention has not yet, so far as I am aware, been called.

Case 1.—R. L., about 40 years of age, was referred to me for advice concerning an affection of the thumb which had existed for three years, in spite of much and varied treatment. The disease consisted of an irregularly outlined, noticeably elevated, bluish-red patch, whose surface was covered with numerous small papillæ and scanty adherent grayish and brownish scales, occupying the greater part of the extensor surface of the terminal phalanx of the right thumb. This wart-like patch was surrounded by a smooth violaceous border about an eighth of an inch wide, less elevated than the patch itself. The thumb-nail was also considerably deformed, the imperfect growth of the nail being due to the manner in which the disease began, to which further reference will be made. On close examination a number of small openings could be seen between the papillæ which studded the surface, from which pressure caused a few drops of thick pus to escape; pus could also be pressed out from beneath the nail-fold at the root of the nail. The history of the malady, obtained from the patient, was as follows:

About three years previously the root of the nail became red, swollen and slightly painful, and remained so without material change for some months. Gradually the skin of the thumb became thickened, violaceous in color, and finally covered with small papillæ from between which, in places, cheesy pus could be expressed. Pain was never at any time a prominent symptom, and the patient was annoyed quite as much by the unsightly appearance of the member as by any disagreeable sensations in it. The patient's general health was far from good; he had a chronic cough, somewhat paroxysmal in character and accompanied by free expectoration; he was hoarse, and had been losing flesh for some months past. The treatment consisted in the destruction of the entire patch by means of a plaster containing 40 per cent. of pyrogallol, which was followed by an ointment of resorcin—1 to 16—until cicatrization occurred. An apparent cure was thus obtained within three or four weeks; but two months later there was a slight relapse, two split pea-sized, brownish-red translucent nodules appearing in the cicatrix. It is of interest to note that these nodules presented the typical "apple jelly" appearance of lupus vulgaris, indicating, if this were any longer a matter of doubt, the etiologic identity of these two clinically quite distinct forms of cutaneous tuberculosis. As to the mode of inoculation in this particular case, it was noticed that the patient was in the habit of frequently biting his thumb, unconsciously, and this habit taken in connection with the

chronic cough and progressive loss of weight suggests a possible way in which the skin may have been inoculated. The chief point of interest, however, is the form which the malady assumed in its early stages. It began as a paronychia, and remained such for some months without showing any of the features characteristic of cutaneous tuberculosis. Some six months after coming under my care the nail-fold about the root of the left index finger became red, swollen and moderately painful; after a time, minute openings made their appearance in the swollen tissues, and a small quantity of thick pus escaped. This affection of the index finger did not differ in appearance from ordinary paronychia, but was absolutely uninfluenced by the treatment advised—application of mercurial ointments chiefly. The patient, who was a more than ordinarily intelligent person, declared positively, that the disease of the thumb began in a precisely similar manner. I think it is evident from this case that we must include among the manifestations of cutaneous tuberculosis a form of chronic paronychia, which in its early stages at least resembles, clinically, paronychia due to other causes.

Case 2.—T. B., 44 years of age, employed by a railway company to clean freight cars, in which live stock had been transported, came under observation in November, 1896, having upon the back of the right hand, near the metacarpo-phalangeal joint of the index finger, a circular elevated patch in which were a number of pin-head-sized openings, some of which contained small horny plugs which could be picked out with the forceps; others gave exit to a drop of pus when pressure was made upon the lesion. This patch had existed for some months, was only slightly painful, and was slowly growing larger. It had followed a slight injury to the hand received by knocking it against the end of a board while cleaning a cattle car. This trifling wound had at first promptly healed, but later became slightly painful, swollen and gradually assumed its present aspect. The patient was in excellent general health, weighing about 175 pounds, and so far as could be learned, had never been seriously ill. After his first visit the patient was not seen again for a considerable time: and upon a second later examination the patch was seen to have undergone a notable alteration in its appearance. Beside having increased in size, its surface had become verrucose, and the horny plugs spoken of had disappeared. The diagnosis of tuberculosis cutis having been made, the lesion was destroyed by the application of a strong pyrogallol plaster for ten days, a 20 per cent. resorcin plaster being afterward employed. Within one month a complete and permanent cure was obtained. The patient was seen one year later and the hand was perfectly sound; but his general health had changed very greatly for the worse. He was emaciated; had a persistent and frequent cough, accompanied by abundant expectoration; his midday temperature at the time of this examination was 101.5 F. Examination of his chest revealed decided dullness at the left apex with numerous râles.

In their paper published in 1886, Riehl and Paltauf called attention to the resemblance, in some cases, between their tuberculosis cutis verrucosa and the "*perifolliculite suppurée et conglomérée en placard*" described by Leloir; and in the case just reported the resemblance to this form of folliculitis was so marked that the diagnosis was for a time in doubt. In the more recent descriptions of this form of tuberculosis by other authors, little or no mention is made of the possibility of confounding these two affections; but the resemblance may, at times, be so close as to make the possibility of error considerable. A microscopic examination of an excised portion of the patch in this case showed that the follicles were markedly involved in the morbid process, there being numerous milium abscesses in the perifollicular parts which communicated in some cases with the follicle. The macroscopic and microscopic appearances justify the assumption that the malady began as a perifolliculitis, and later invaded the interfollicular tissues.

Case 3.—The last case I report—in some respects the most interesting of the three—is unfortunately very defective in its clinical details, since I have been able to procure but very few facts as to its history, which is as follows:

Mrs. F., aged 67, had a circular, considerably elevated, wart-like lesion, the size of a quarter, which had existed for about one year upon the flexor surface of the fore-arm, about two inches above the wrist. This, according to her statement, had begun as a small "pimple," which steadily enlarged and became covered with numerous enlarged papillæ. The entire lesion, together with a portion of the surrounding tissues, was excised and submitted to me for microscopic examination. The excised lesion presented the macroscopic appearances of a verrucose tuberculosis, but having been in alcohol for some days before coming into my hands, a positive diagnosis from the naked eye appearances was somewhat difficult. Examination

of sections showed a considerable increase in the horny layer of the epidermis, numerous plugs of cornified epithelium in the follicular ducts, enlargement of the papillae of the corium, particularly in the longitudinal direction, and many down-growing, branching prolongations of the interpapillary portions of the rete. In the corium were numerous areas of round and epithelioid cells with a moderate number of multinucleated giant-cells. In addition to these were many variously sized tracts of epithelial cells. In short, while there were the usual histologic features of tuberculosis of the skin, there was also the epithelial proliferation characteristic of epithelioma, so that we may conclude that we have here one of those infrequent cases in which a tuberculous lesion becomes the seat of malignant epithelial proliferation.

Marked increase of the interpapillary prolongations of the rete are common in lupus vulgaris; but in infrequent cases the tuberculous tissue or the cicatrix at the site of an old tuberculous lesion becomes the seat of actual epithelioma. Desbonnets, who has recently studied this subject, was able to collect the reports of eighty-six cases in which epithelioma occurred either in the lupus tissue itself or in the scar of lupus, but in only a single one of these cases was the verrucose form of tuberculosis cutis associated with epithelioma. According to this author this form of epithelioma may assume the vegetating or ulcerative form, and is more rapid in its progress than that occurring in non-tuberculous tissue.

In conclusion, these three cases illustrate: *a*, a form of paronychia chronic in course, tubercular in origin, terminating in a verrucose tuberculosis of the skin; *b*, the follicular origin of some of the cases of tuberculosis cutis; *c*, the concurrence of tuberculosis cutis and epithelioma.

DISCUSSION.

Dr. CAMPBELL—I saw a case of the disease which had involved the middle finger and right patella. There was no history of tubercular infection, nor were there any lung symptoms. The eruption had continued for three years. I used guaiacol with good results.

Dr. GOTTHEIL—I have noticed, in some patients, purplish patches occurring on the hands which lasted for years. Atrophy of the tissues followed, but no ulceration.

Dr. SHOEMAKER—I recall one case of tuberculosis cutis which was atypical and the diagnosis was made as the result of the condition of the internal organs. I have used tuberculin in seven cases of lupus vulgaris and no good results followed.

Dr. DUHRING—Much confusion has arisen in the writings of surgeons and dermatologists on tuberculosis of the skin. Many descriptions are vague and confounding. They have gone to extremes in their deductions and beyond the old landmarks, and since they have discovered the tubercle bacillus all cases of lesion of the skin where the micro-organism is, or thought to be found, are classed by them simply as tuberculosis cutis. The clinician, and even the pathologist, now becomes very much confused by the various pictures. The material just presented has not elucidated the question. If only 1 tubercle bacillus can be found in 200 sections, as one observer has reported, then I would doubt very much if the tubercle bacillus was the cause. I consider it a great mistake to include all the forms under tuberculosis cutis. I would divide the subject into the two usual heads and then make another class where the presence of tubercle bacilli had been demonstrated and which presented rare clinical forms. Those described this morning would belong to this latter class. Grouping all these varieties under one term, tuberculosis cutis, dispensed with any classification, so that much confusion was now arising. This question of retention of old terms does not interfere with any of the valuable additions made by pathologists, but I am opposed to doing away with valuable clinical pictures which have been used so long and are so useful for teaching purposes.

Dr. GILCHRIST—I recall two cases of pseudo-tuberculosis of the skin where the tubercle bacilli were absent, but in their place were found blastomycetes, bodies allied to yeast fungi. In the second case, pure cultures were obtained and successful inoculation in numerous animals carried out. Examinations of the tissue from all tubercular cases for blastomycetes should be made. A simple method of demonstrating the presence of these organisms is by soaking the unstained

sections in liquor potassæ when the blastomycetes appear as refractive, doubly-contoured bodies, whereas the tissue becomes blurred. I do not consider any case of cutaneous disease tubercular until the presence of tubercle bacilli has been demonstrated. The best plan for detecting the presence of tubercle bacilli in lesions of the skin is by a smear taken from the lesion on a slide, then dry and stain in the usual way. There is a much better chance of finding the organism by this method than seeking for them in sections.

With reference to the variety of tubercle bacilli in tuberculosis lesions, smear preparations will probably demonstrate the presence of larger numbers. It has been lately thought that some tubercular cutaneous lesions might be due to the effect of the toxins of the tubercle bacilli and not entirely due to the presence and growth of the bacilli themselves. One authority has expressed the opinion that lupus erythematosus might be due to the toxin alone.

In numbers of cases there is a great similarity between tubercular and syphilitic lesions of the skin, and one can then only make a diagnosis by further examination for the presence or absence of tubercle bacilli. In the sections from milium gumata the pathologic picture is very like that of a typical tubercle. With reference to tuberculin, it has been used in the Johns Hopkins Hospital with negative results.

Dr. RAVOGLI—Tuberculin was used, at first, as an aid to diagnosis, but I then noticed its good results and have continued its use.

Dr. HARTZELL—I reported the three cases because they were different from the usual type. The diagnosis of tuberculosis cutis was made, but the presence of tubercle bacilli was not demonstrated. I tried the test for blastomycetes, but they were not present, so this disease was excluded in the diagnosis. I believe in retaining the old clinical classification of tuberculosis of the skin. Lupus vulgaris represents a distinct clinical picture, but tuberculosis cutis is also a definite term.

ANGIOMATOSIS, WITH LESIONS OF THE SKIN AND MUCOUS MEMBRANE.

Presented to the Section on Cutaneous Medicine and Surgery, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY J. F. SCHAMBERG, M.D.

ASSOCIATE IN DISEASES OF THE SKIN IN THE PHILADELPHIA POLYCLINIC. PHILADELPHIA, PA.

J. B., aged 80, came under observation about nine months ago. He is both physically and mentally infirm, the latter preventing me from obtaining any history concerning the duration of the lesions presently to be described. The patient sought medical aid on account of an "itching of the body."

There is great relaxation of the muscular tissues of the body, as is evidenced by the existence of ventral and inguinal herniæ. The patient has also multiple lipomata of the forearms, a pedunculated fibroma on the left thigh and numerous small vascular nævi scattered over the trunk.

The itching of which the patient complained, is the result of a discrete inflammatory papular eruption distributed extensively over the trunk and extremities. This eruption is indistinguishable from an ordinary papular eczema. Upon the inner aspects of the thighs, however, are papules of a deep red color which do not disappear upon pressure and which resemble small angiomas.

The condition of interest is situated upon the scrotum. This is the seat of numerous pin-head to split-pea-sized violaceous and bluish elevations. They are more numerous on the antero-lateral aspects of the scrotum and are arranged in a linear manner, apparently following the lines of the superficial veins. Hyperkeratosis is entirely absent, the summits of the lesions being smooth and soft. No subjective symptoms are present.

Lesions of a similar nature are present in the mouth. On the buccal mucous membrane of the left

side are numerous bluish, pin-head-sized tumors. A few small discrete lesions are present upon the right side. On the internal aspect of the left oral commissure are three purple, split-pea-sized, aggregated elevations. The inferior surface of the tongue presents a varicose appearance and is the seat of numerous lesions of the same nature as those described above. They are for the greater part studded along the outer borders of the lingual veins, which are distinctly enlarged.

Around the orifices of the duct of the sublingual gland are grouped a half dozen small angiomas.

Upon the palpebral border of the right lower eyelid is a circumscribed enlargement of capillaries resembling an angioma in course of development.

Biopsies were made upon two occasions, an inflammatory papule from the thigh and a small angioma from the mouth being excised. It was the intention of the writer to remove also a lesion from the scrotum for histologic examination. The sudden demise of the patient, however, prevented all further study of the case.

The sections were hardened in successive strengths of alcohol, imbedded in paraffin and stained with hematoxylin and eosin and picro-carmin.

The papule from the thigh exhibited under low power a moderately intense leucocytic infiltration of the papillary and subpapillary regions of the corium. The papillary blood vessels are enlarged and surrounded by a round cell infiltration. Dilated lymph spaces are present in the subpapillary layer. The epidermis appears to be normal.

The lesion from the buccal mucous membrane presents the following appearance:

The rete mucosum seems to have an unusual depth, and yet it can scarcely be said that it is hypertrophied. The epithelial layers above present no unnatural thickening. The body of the tumor is made up of loose fibrous stroma containing blood vessels. The number of blood vessels is greatly augmented and their caliber increased from two to twenty times their normal diameter. Some of these run directly upward and seem to penetrate the malpighian layer. The majority, however, slope upward to the summit of the tumor, being lost in a number of loosely arranged rete cells. In the lower part of the rete mucosum, and just above the central summit, is a large oval blood space. Arched over this is a layer of flattened, elongated cells which seem to belong higher up in the tissues.

There are no signs of inflammation.

As intimated in the title of the paper, the writer prefers the designation of "angiomatosis" rather than "multiple angioma." The former name indicates the presence of a tendency to the formation of angiomas, and this tendency was certainly manifest in the present case. Angiomas were present upon the scrotum, the conjunctival mucous membrane and in the mouth.

A cavernous angioma is always the result of a weakened condition of the vessel walls, and its formation is favored by the proximity of large veins. I saw recently similar angiomas upon the inner aspect of the foot, in a woman with marked varicose veins of the leg. Cavernous angiomas are not at all uncommon in the livers of elderly individuals. Pathologists agree in attributing this condition to varicosity of the veins of this organ.

The arterio-sclerosis accompanying senility was the primary etiologic factor in the case under considera-

tion. The localization upon the scrotum and the inferior surface of the tongue was determined by the varicosity of these regions.

So far, scrotal angiomas have only been observed in individuals past the age of 50.

But one instance of a similar case has, to my knowledge, been published, and in that case the condition was localized to the scrotum. At a meeting of the American Dermatological Society, in 1896, Dr. Fordyce of New York read an article on "Angiokeratoma of the Scrotum." His chromo-lithograph represented a condition identical with my own case. I do not believe that the name "angiokeratoma" was justified in the above instance.

After all, angiokeratoma is merely a compound process, a super-position of keratosis upon ordinary angioma. Whenever the lesions are located upon parts where keratinization is normally active, as upon the hands, we have a hyperkeratosis. Upon other parts, no such process is superadded. Angiokeratoma is observed only upon exposed regions, and particularly the hands and feet. The etiologic factor in these cases is repeated chilblain, which serves to weaken the vessel walls by producing an arterio-sclerosis.

Angioma of the scrotum is not as rare a condition as the paucity of recorded cases would seem to indicate. Dr. Hyde of Chicago and Drs. Morrow and Klotz of New York informed me that they had each observed cases of this peculiar affection. Furthermore, as the condition is unattended by any subjective phenomena, there exist no doubt many cases that are never seen by the physician.

The conclusions to be drawn from this paper are as follows:

1. Arterio-sclerosis is a prerequisite to the formation of cavernous angiomas.
2. This condition of the vessel walls may result from senility, repeated chilblain and other causes.
3. The term angiokeratoma should be restricted to the cases in which the keratosis is a prominent feature.
4. There may exist in the aged a tendency to the formation of angiomas upon the cutaneous and mucous surfaces.

THE TONGUE AS IT INTERESTS THE DERMATOLOGIST.

Presented in the Section on Cutaneous Medicine and Surgery, at the eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY C. W. ALLEN, M.D.

Consulting Dermatologist to the Randall's Island Hospitals, the Instituto Italiano, and Holy Rosary Asylum of New York; the Hackensack and the Bayonne Hospitals of New Jersey; Consulting Genito-Urinary Surgeon to the City Hospital and Attending Surgeon (Department of the Skin) Good Samaritan Dispensary, New York.
NEW YORK, N. Y.

For a number of years I have made note in my case books of the appearances presented by the tongue in dermatologic, syphilitic and other cases, and have been impressed with the relative frequency with which this organ is involved in one way or another.

At times the tongue lesion has no connection with or bearing upon the skin affection under treatment, while at others, and habitually in syphilis, it has important bearings. The subject is so large I must content myself with generalities and general conclusions.

The statistics I present cover several series of observations made at intervals covering a period of ten

years. Thirty-nine hundred tongues were examined with the object above mentioned.

The importance of diagnosis in affections of the tongue need not be dwelt upon in addressing men who are constantly seeing the ravages produced in neglected cases of syphilis, tuberculosis and leucophakia going on to cancerous development.

The tongue has not, however, received the study its importance calls for in the more benign affections closely allied to or identical with cutaneous diseases.

The surface of the organ has such close similarity to the skin's surface that it is not a matter of surprise that analogous disease processes attack both, or that it is to the dermatologist that tongue cases are so frequently referred by general practitioners. Many skin diseases present simultaneously their effervescences upon this organ's surface, and indeed the lesions may appear here before they develop upon the skin. This is true at times of pemphigus, variola, varicella, lichen planus and syphilis.

At other times the tongue will give the cue in obscure instances.

The differential diagnosis between scarlatina and surgical scarlet or septicemia, can at times be established by the brownish or *café au lait* furring in the latter giving way to a smooth glazed surface, or one over which large rounded papillæ stand out like a bed of mushrooms.

In varicella presenting so few lesions upon the skin surface in an early stage, that diagnosis is doubtful, a group of lesions on the tongue consisting of round yellowish white, firm-looking lesions, interspersed with rounded excoriations corresponding to the vesicles whose walls have ruptured and become rubbed off, is at times so characteristic as to remove all doubt. Such a group may be found beneath the tip, in which situation I have observed a group of six separate vesicles. The fleshy-appearing papule is to my mind the characteristic feature of these tongue lesions of varicella.

In variola an early vesicle may be found upon the tongue, though more commonly in the roof of the mouth.

A vaccine vesicle has been observed upon the tongue (*Journ. C. and G. U. Diseases*, 1889, p. 359).

Vesicles are also to be observed in impetigo herpetiformis, as in Hartzell's case, reported at the last American Dermatological Association meeting; in pemphigus and in burns from taking too hot water into the mouth. These may go on to ulceration.

Herpes occurring upon the lips is accompanied at times by vesicles whose walls are naturally of short duration and the lesions are usually observed first in the stage of excoriation. It is confined almost entirely to the tip and anterior edges of the tongue, and the lesions are red, tender and slightly indurated.

The differentiation is to be made from a form of recurrent herpes in syphilitics in which the lesions are of various size and upon the dorsum as well as the edges. They occur mostly in smokers, in those taking mercury by the mouth and in whom the mouth hygiene is not good. The succeeding areas are polycyclic.

The list of skin diseases which may at times present actual lesions upon the tongue is large. Confining myself to those that I have seen or those that have been recently reported, I enumerate: Leprosy, syphilis, lupus vulgaris, lupus erythematosus, lichen planus, lichen ruber, dermatitis exfoliativa, pemphigus, herpes, ringworm (Kinnear)? purpura, purpura hemorrhagica, keloid, vascular nevus, xanthoma, crsipelas, anthrax,

Addison's disease, myxedema, zoster (Fournier), xeroderma pigmentosum, urticaria, eczema, eczema seborrhoicum, impetigo, filaria medinensis (Guinea worm disease), impetigo herpetiformis (Hartzell), ichthyosis? erythema multiforme (Crocker), molluscum fibrosum (Crocker), pityriasis rubra (U. S. Navy), dermatitis herpetiformis, angio-neurotic edema, one-sided swelling, keratosis follicularis (?), angioma, phthiriasis (pigmentation).

The terms ichthyosis, psoriasis, keratosis and tylosis may best be dropped in discussing and describing lingual leucoplasias.

Leucokeratosis is a term at once sufficiently comprehensive and descriptive under which the various forms of white plaques may be included, and need occasion no confusion as to the identity of a given process with any dermatosis known by the same name. Leucokeratoses especially interest the dermatologist, since their frequent occurrence in the stages consecutive to that of acute infection from lues brings up constantly the question of differential diagnosis. The importance of the latter lies in the well known frequency with which leucoplasias of benign aspect, existing for years without inconveniencing the patient, suddenly assume malignant features and necessitate amputation of the tongue, in whole or in part, to preserve life. The question of treatment in the early stages and the methods best adapted to prevent this unfortunate ending, comes up before the dermatologist for solution. I can not enter into the opposing views as to the advisability of early radical operation, or of leaving such plaques wholly without treatment and preventing so far as possible irritations which may hasten malignant degeneration. My personal experience leads me to believe that smoking, the use of alcoholics, faulty mouth hygiene and mercurials administered by the mouth play a most important rôle in the development, continuation and recurrence of luetic and paraluetic white plaques in late stages of the disease.

In the non-specific forms mild applications do harm rather than good, and such means only as will destroy the plaque *in toto* should be resorted to. At the earliest manifestation of cancerous change, excision widely beyond the clinical limits of the plaque should be performed. The signs of danger should include papillomatous outgrowths, ulceration and fissuring.

A condition of frequent occurrence in skin cases is that presenting wandering rings and plaques, best designated *exfoliatio areata lingue*, but commonly known by the misleading name of ringworm of the tongue. While it may occur in subjects of ringworm it has no more to do with the skin affection than it has with lupus, leprosy, syphilis, psoriasis, eczema, eczema seborrhoicum, keratosis pilaris, rosacea, and impetigo contagiosa, in all of which conditions I have seen it, as well as in the exanthematic fevers. Its importance is chiefly derived from the fact that Parrot taught that it was a manifestation of syphilis when seen in children. I have convinced myself, from many instances in absolutely non-specific cases, of the fallacy of this view, and I can unhesitatingly pronounce it erroneous. It is often present in several children of a family. That this geographic tongue is not universally known as it should be I may cite a recent communication to the *London Lancet*, asking the meaning of a map-like appearance of the dorsum lingue which the writer had observed a number of times in young children.

The term glossitis often used in speaking of it is not applicable, since there is no inflammation and in

many instances absolutely no subjective sensations attending the condition unless green nuts, strong acids and the like are eaten. The yellow ring-like border may extend upon the under surface of the tongue and independent rings may here develop, contrary to the statement in books. I have seen it undergo spontaneous cure and have observed it so frequently in adults who assured me that during their whole life they had never seen it present before, that I must believe it capable of developing at any age. It is most frequent in those whose tongues are naturally fissured in many directions and of uneven surface. The statement made by authors that it is chiefly an affection of infancy is also not strictly correct, since a fairly large percentage is noted in adults.

Stomatitis aphthosa implicating the tongue interests the dermatologist, because it not infrequently happens that lesions due to the affection occur upon the skin surface about the mouth, and Hertwig has recorded an observation of the identical eruption upon the hands from drinking infected milk.

Stomatitis ulcerosa as it occurs in scorbutus and in mercurial salivation comes to, if the latter is not laid at, the door of the dermatologist and syphilographer. The conditions brought about by those and similar causes for systemic depression favor the activity of mouth organisms in an ill-directed way. The ulcer of stomatitis is irregularly rounded and grayish. Tuberculous ulcer is not, as usually stated, invariably painful.

The tongue in syphilis.—The tongue furnishes one of the most reliable means of diagnosing syphilis, past or present. The frequency of mouth lesions in all stages of syphilis is well known. To determine what this frequency is, I have taken 100 consecutive histories of syphilitic patients from my office records and find that in just 50 per cent. mouth lesions are noted. Those of the tongue are for the most part mucous patches and recurrent leucomas, but include five instances of specific leucoplakias; one of gumma of the tongue; one of exfoliative glossitis; three of fissures. In two instances there was present that peculiar wandering ringed condition which I think is best named *exfoliatio areata lingue*, and which has nothing to do with syphilis in any except an incidental way. There exists, however, a very similar exfoliation due to syphilis, occurring as one or two smooth patches, usually upon the dorsum, in the early consecutive stage. These have no limiting yellowish ring and are stationary; last for a long time, and subsequently leucomatous plaques often occupy the areas covered by them.

The lymphatic tissue at the base of the tongue has a very decided interest to us, since it may not only undergo important changes in the early stages of lues, giving rise to hemorrhages, cough, etc., but the diagnosis of the elevated projecting teat-like follicles separated by furrows which form the "lingual tonsil" must be at times differentiated from malignant new growth and from vascular tumor which sometimes develops in this situation from angioma and varix.

Specific leucokeratoses are not always easily differentiated from non-specific. A man came to me several years ago, presenting about the center of the dorsum a rounded elevated papillary white plaque. The entire dorsum surrounding this island was red, glazed and somewhat sensitive. There was no history of syphilis, but one of a soft sore and suppurating bubo having occurred at the age of 17 years. Sub-

sequent observation and treatment proved its specific nature. Small painless, pearly patches along the edges of the tongue are usually specific.

A beginning leucoplakia is often hard to distinguish from a condyloma or hypertrophic papular plaque.

In one instance of leucoma occupying the tip and anterior margins, extending slightly to the inferior surface, in a man who smoked about thirty cigarettes daily and who denied syphilis, I was for some time in doubt as between smoker's patch alone or smoker's patch plus lues. The general surface was smooth and grayish, but in places there were radiating whitish lines which decided me in the latter view.

The luetic plaque as well as the non-specific may degenerate into cancer, though the former more rarely does so.

The small white, rounded or oval plaques which so constantly occur in some subjects of late lues, and which are removed and prevented with such difficulty while the patient continues to smoke and drink alcoholic beverages, and even in the absence of these habits while mercurial treatment by the mouth is persisted in, I have found to be readily managed under treatment by intra-muscular injections of soluble salts of mercury. Stomatitis "luetica" is often only an evidence of a depraved state of constitution in which the active agent of lues plays little or no rôle.

Psilosis, a condition of the tongue which might readily be mistaken for syphilis, has been described by Thin as occurring in the tropics and affecting those suffering from intestinal disorders. I have seen an instance resembling it in a gentleman suffering from chronic dysentery contracted in India who came under my care upon arriving in New York. At first the lesions are much in the nature of herpes, leaving denuded areas. There are subsequently formed deep clefts and the dorsum is cut up into glazed areas.

Chancre of the tongue.—The tongue holds the third place in frequency of location of primary syphilis of the mouth. It may be single or multiple, and most commonly near the tip. It is rounded, elevated and soon becomes ulcerated, though marked induration may not occur, or the chancre may be of the erosive or fissure type. The diagnosis may have to be postponed until the consecutive roseola appears, and at times the differentiation from a mucous patch is scarcely to be made. From chancroid the diagnosis is made by the relative infrequency of the latter and by the result of inoculation.

Emery and Sabouraud have recently reported a chancroid of the point of the tongue occurring simultaneously with chancroids of the penis, having the same appearances, running the same course, giving the same inoculation results and accompanied by bubo.

The bubonic enlargement which accompanies chancre is of early development, involves several glands as a rule and does not suppurate.

Gumma is not uncommon when we take into account those nodules of small size located far back upon the dorsum which only careful inspection brings to light. The diagnosis from incipient epithelioma may be closely simulated when a single gumma has a lateral situation. Deep-seated gummous tumors within the parenchyma may have to be differentiated from abscess, foreign body, intramuscular tuberculosis, epithelioma, sarcoma, myxoma, adenoma, lipoma, fibroma, angioma and cystoma, all of which neoplasms occur in the substance of the organ. Gumma is more frequent in men than women, usually has a central situ-

ation, is accompanied by other signs, tends to ulcerate and melts away under iodid of potassium, establishing the diagnosis in a positive manner.

The intra-lingual tuberculous hard nodule always arises in the muscular, gumma in the connective, tissue. It is an earlier form than the superficial ulcerating tuberculosis.

Lichen planus is at times limited to the tongue. I have never observed an instance, but have had one case referred to me in which the only other portion of the body affected at any time before or since, so far as I know, was the glans penis. This case was very promptly cured by gradually increasing doses of arsenic, and so far as I am informed there has been no recurrence. A similar instance has since been reported by Hallopeau and Schroeder. Here, however, the buccal membrane was coincidentally affected with the glans. The diagnosis rests between this disease, leucoplasia and syphilis.

The characteristic appearance is one of radiating or star-shaped lines of pearly hue, indolent and not pruritic. If lesions occur upon the tongue as they often do when the skin surface is freely covered, the diagnosis is not difficult and, as Fournier believes, the wafer-like appearance of dull white character is as characteristic as the striated plaques.

Lichen ruber.—According to Unna this is capable of producing lesions upon the tongue in the form of multiple erosions. These differed wholly from the sharply defined, white, rounded or slightly irregular spots of lichen planus.

Dermatitis exfoliativa is thought by Brocq to be accompanied by irregular white plaques due to the same general process as that affecting the skin.

Zoster of the tongue must be regarded as a rarity. Fournier has recorded one instance.

Herpes is of common occurrence both in the acute and chronic recurrent forms. It accompanies certain instances of herpes febrilis of the lips, or occurs as an independent recurrent affection. The vesicular stage is so brief that a distinct wall is scarcely ever to be seen. A red tender round denuded spot marks the vesicle's site, and surrounding it may be an area of slight induration. The tip and edges are the parts affected.

In recurrent herpes the lesions may not be much larger than a pin's head, but a group often gives a polycyclic outline to the inflamed patch.

Pemphigus may first show itself by the occurrence of a bulla upon the tongue, and in the course of the disease tongue lesions have occasionally been observed. That the bullous wall is much less ephemeral than is usually the case with vesicles I am convinced by observing a number of times a hemorrhagic bulla with intact walls, from an unknown cause, in an old syphilitic.

Erythema exudativum multiforme.—According to Rosenbach (*Deutsche Med. Wochens.*, June 28, 1894), all local pemphigus of the tongue, so-called, is strictly speaking an erythema bullosum and is often accompanied by a similar eruption about the genitals. This combination of tongue and glans penis eruption as seen frequently in lichen planus, might lend weight to this opinion.

Probably some of the cases belong in that class of hereditary predisposition to bullous formation now so well known under Köbner's designation of *epidermolysis bullosa hereditaria*.

Lupus of the tongue alone is rare. In association with lupus of the contiguous mucous membranes and

skin it is not uncommon. It occurs mostly upon the posterior portion near the epiglottis, as small isolated nodules having a soft granular surface.

When it ulcerates the tuberculous sore is simulated, but the steadily progressing ulcer is free from painful sensations. Spire reported fourteen observations upon tongue lupus (*Archives Cliniques de Bordeaux*, 1895), adding three of his own, and a number have been added since then; Audry reporting two cases, in one of which the point of the organ was alone implicated. There may occur a group of tubercles, the center being more elevated than the periphery, and surrounding this may be a somewhat raised limiting band of tissue. There is little tendency to ulceration and so little discomfort may be caused that the patient is scarcely aware of the plaque's existence.

Lupus erythematosus is more rarely seen, though its occurrence upon the lips and inner surfaces of the cheeks is not so unusual in connection with its appearance upon the face. Elliot has shown a case at the New York Dermatological Society.

The appearances upon the vermilion border of the lips is much the same as upon the skin surface, but where continually moist the appearances are more those of a diffuse margined mucous plaque.

Impetigo contagiosa is said to occur upon the tongue. I am not sure that I have seen it, though I have recently observed an instance of exfoliatio areata in a child with impetigo of the face.

Sevestre and Gaston (*Bul. de la Soc. des Hôp.*, 1891), speak of an impetiginous stomatitis, in debilitated infants having impetigo, as well as intestinal and other disorders. The staphylococcus aureus was found in eight instances.

Purpura I have noted in a number of instances of purpura simplex and in one case of hemophilia dating from the age of 3 years.

Lepra may present tubercular lesions, fissures, groups of small papilliform tumors in rounded or oval plaques and conditions of chronic glossitis very similar to those of syphilis.

Urticaria may produce serious enlargement of the tongue. I have seen the organ so swollen in giant urticaria, following the use of some of the coal tar antipyretics, as almost to cause suffocation.

A distinct wheal upon the tongue is said by Laveran to have pointed to the correct diagnosis in an obscure suffocative affection of the throat at a time when the cutaneous surface was free.

Neroderma pigmentosum lesions have been observed by Keating upon the tip of a child's tongue.

Xanthelasma may show one or more soft raised patches upon the tongue. The color is yellowish white, but under the microscope the appearances are said to be identical with that of disseminated skin xanthoma (*Lancet*, Feb. 7, 1874).

Keloid has been observed in subjects of cutaneous keloid. I have within the past year, seen a young woman with two rosy plaques of spontaneous keloid upon the chest, who also had a hard nodule in the substance of the tongue projecting slightly above the surface, which might well be of the same nature of growth.

Leucokeratoses.—Aside from the numerous leucomas of syphilis the dermatologist is frequently called upon to pass judgment upon a bluish-white or silvery plaque of the tongue which is not specific. If it be a beginning plaque the diagnosis is required; if of long standing advice as to removal or treatment.

The great tendency shown by the tissue of these plaques to undergo cancerous degeneration is ever to be borne in mind.

Treatment.—While it is possible for certain superficial, soft, pliable, bluish-white leucomas to disappear spontaneously or under local and constitutional treatment, the thicker and older plaques rarely if ever do so. There are those who maintain that every leucomatous plaque should be cured, if possible, even by surgical means if necessary, because of the danger from tongue cancer. While I am not prepared to admit that the resulting cicatrix and deformity, which may prove an object of irritation and be subject to many of the same dangers as was the original patch, is greatly to be preferred to a plaque which gives no trouble, still I am strongly of the opinion that all such tongues should be regularly inspected by a physician, and a radical operation undertaken at the first evidence of approaching danger. Perrin regards the best line of treatment in any case to be the total destruction of the white patch with the thermo-cautery or the galvano-cautery, and such a course seems to me much to be preferred to any attempt to remove the plaques by acids or other caustic applications.

[The reader showed a series of water-color drawings in illustration of certain affections mentioned.]

DISCUSSION.

Dr. GOTTHEIL—There is no account of lesions of the tongue from the dermatologic standpoint. Water-color drawings or colored sketches are very insufficient. I have made models in clay and wax of the open mouth and tongue and molded them as near nature as possible. A series of models of diseases of the tongue would be of great value.

Dr. CAMPBELL—In syphilitic lesions of the mouth, if they do not yield to the usual mode of treatment, will promptly do so to hypodermic medication. Locally I also use chromic acid from 2 up to 20 per cent. in chronic cases, and it has acted very successfully.

Dr. BULKLEY—I have used this method for years up to a 4 per cent. solution. Its application also checked mucous patches.

CASE OF PRIMARY COMBINED COLUMN DISEASE.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY JOHN K. MITCHELL, M.D., AND
J. H. WALLACE RHEIN, M.D.

PHILADELPHIA, PA.

The patient, A. R., a farmer, when first seen Jan. 19, 1895, was 42 years of age. He had never suffered from any serious disease, had led a moderate life and denied syphilis. His hair was almost white but his complexion clear and unwrinkled. Four months previously (September 1894), he began to be troubled by numbness in the toes and fingers, which became worse after the first of December, 1894. His condition when first examined January 19 was as follows: He complained of numbness of both legs and of the body up to the manubrium. There was a subjective sense of numbness of the left arms and in a slighter degree of the right, ill-defined, but felt to and above the elbows.

There were girdle pains in the lower abdomen, slight swaying on standing, but no staggering when walking; and a decrease of sexual desire. The knee-jerks were active, and sensation everywhere to touch, pain, heat and cold was good. There was slight pain on pressure over the third dorsal vertebra. No difficulty with the bladder or rectal sphincters was ob-

served. By March, 1895 (under treatment with iodids, faradism and massage) the numbness had disappeared. There was still a sense of tightness about the knees and ankles. During the summer he improved very much in his general condition. In November, 1895, there was some disturbance of the bladder and rectal functions. The knee jerks, which in January had been normal or slightly increased, were now decidedly exaggerated and ankle-clonus was present on both sides. The station too was not quite so good as before. Sensation to touch was still normal in the hands and feet, and it was not until January of the next year (1896) that he began with some suddenness to grow more and more uncertain on his feet. The girdle pain increased and with a sense of tightness about the knees and ankles there was marked weakness of the lower limbs. From that time until his death there was progressive failure of motion and sensation. He was soon confined to his bed, when bed sores developed rapidly; there was bladder and rectal incontinence; he had at last vomiting whenever food was taken and finally died, much emaciated, from exhaustion. For some weeks before his death no knee jerks or clonus could be developed.

The diagnosis was made at first as congestion of the cord, with a possible indication of tabes. Upon the development of the acute symptoms this was reconsidered and the case held to have been a slight chronic myelitis, with acute inflammatory symptoms superimposed, but this opinion had again to be changed in the light of the histologic study.

Autopsy was made six and a half hours after death. The body was extremely emaciated, the abdomen distended with gas, extensive sloughing of the back and buttocks was present, and postmortem discoloration of all the dependent parts. There was moderate rigor mortis.

On removing the spinous processes, the cord-membranes were found baggy and distended with an excess of cerebro-spinal fluid. The dura was not unduly adherent to the vertebral canal. The membranes were dense on section. On cross-section the cord was gray in appearance especially in the thoracic portion. This became less marked above in the cervical region and below in the lumbar and dorsal cord. The organs displayed no evidence of general disease. The cord was hardened in Müllers fluid and stained by the Weigert-Pal and Marchi methods and with carmin. The result of the staining by the Weigert-Pal method was as follows:

Cervical enlargement.—In the direct pyramidal tracts beginning degeneration was observed in the right side a short distance from the periphery. On the opposite side the process was nearer the periphery and much more anterior. Though in extent the process was slight in degree it was well marked. Large spaces were visible where the nerve fibers had disappeared, the line between the limit of this process and the tissue which was well-stained, being quite sharp. In the antero-lateral ascending tracts a few spaces were observable anteriorly, but the remainder of these columns and especially the posterior parts were profoundly diseased. The nerve-tissue was entirely destroyed in a large area.

The anterior ground-fibers were fairly well stained, but in the crossed pyramidal and direct cerebellar tracts only occasionally were stained fibers to be seen. This change was most intense in the periphery of the cord. Adjoining the anterior portion of the posterior and the

posterior portion of the anterior horns the tissue had taken the stain well, except at the tips of the posterior horns where there remained but a few stained fibers. The process had progressed equally on both sides. In the posterior tracts not a single healthy fiber remained in the postero-median columns except at the extreme anterior part, just bordering on the posterior horns where a few scattered fibers had taken the stain.

The posterior root zone and the zone of Lissauer were free from disease. The posterior roots had escaped. The fibers of the anterior roots had stained well.

Cervical enlargement, combined sclerosis. (Weigert-Pal).

Upper dorsal cord.—The direct pyramidal tracts displayed a remarkable increase in the extent of disease. All the fibers seemed to be entirely lost. The border line between this extreme degeneration and the fairly well stained tissue was quite distinct though less sharp than in the cervical levels. There were a few spaces now visible in the part of the cord between the pyramidal and the antero-lateral ascending tracts. The process was greater in extent than in the cervical cord. There were fewer fibers that took the stains and larger empty spaces.

The columns of Goll were not so profoundly but more extensively involved than in the cervical cord. A few fibers remained which took the stain. Burdach's columns were severely affected. Large spaces were visible and much less tissue was stained than higher up. The zone of Lissauer still remained free.

Upper dorsal, combined sclerosis. (Weigert-Pal).

Lower dorsal.—A few fibers in the posterior roots had disappeared. The degenerated areas in the anterior pyramidal and crossed pyramidal tracts were separated by a band of lesser degeneration which diminished in degree toward the periphery, although it remained quite intense there, and centrally, where a small number of stained fibers remained, bordering on the anterior horns. In the lateral columns the process was less pronounced immediately adjoining the posterior horns at their peripheral portion but everywhere in the antero-lateral columns there was evidence of disease.

Lower dorsal, combined sclerosis. (Weigert-Pal).

In the posterior columns only a slight band of fibers around the posterior margin of the posterior horns, was stained, except at the posterior internal root-zones which still appeared to have escaped to a moderate degree. Clarke's columns had in large part disappeared, only a few cells remaining.

Lumbar enlargement.—The change in the antero-

lateral columns was now mainly limited to the crossed pyramidal tracts. Anteriorly the anterior marginal tracts of Marie were slightly diseased. The process was quite moderate, many well stained fibers remaining, and fewer spaces were discoverable.

In the posterior columns, many stained fibers were seen in Goll's columns. The stained fibers were greatest in number along the posterior commissure anteriorly and posteriorly, while centrally the degeneration was still very marked.

Burdach's columns were still involved but to a less degree. In the posterior external root-zones appeared many healthy fibers.

Sacral, combined sclerosis. (Weigert-Pal).

Sacral cord.—Remains of the disease in the lateral and posterior columns were seen. The process was least advanced at this level, the affected areas corresponding to the more intensely diseased ones above, but the change was only moderate in degree.

Marchi method; Cervical region.—Recent degeneration was present to a slight degree in the direct pyramidal tract, especially around the seat of the old sclerotic change. In the lateral tracts the degeneration was intense, mainly confined to a broad band encircling the sclerotic areas. The part around the focus of old degeneration was intensely involved.

In the posterior columns there were degenerated fibers found scattered everywhere, but the process was most intense on either side of the postero-median fissure, at the central and peripheral portions of the columns of Goll.

Middle dorsal, combined sclerosis. (Weigert-Pal).

Dorsal region.—The degeneration in the anterior pyramidal tracts was more intense and degenerated fibers were visible in greater numbers in the anterior portion of Gower's columns. In the other portions of the cord the same condition existed as above described, except that the process was more intense. A few degenerated fibers in the posterior horn which could be traced into the anterior horn were seen.

The Westphal "Wurzel-eintritt" zone was comparatively free, but a few degenerated fibers existed. In the lower dorsal region, where it will be remembered the chronic process was farthest advanced, there was a corresponding prevalence of acute degeneration.

Lumbar and sacral regions showing acute degeneration. (Marchi)

Save the postero-median root-zones, which were but slightly involved, the whole transverse section of

the cord was dotted with coagulated myelin, especially in the areas around the old degeneration. Many fibers running into the anterior horns were degenerated.

Sacral region.—The acute degeneration was much less extensive than either in the dorsal or cervical regions. The Westphal-eintritt zones were especially degenerated, the reflex collateral of Koelliker being profoundly involved. These degenerated fibers were easily traced far into the anterior horns. In the anterior part of the cord the degeneration was mostly in the periphery bordering on the antero-median fissure but scattered degenerated fibers were found everywhere. The process was quite marked in the crossed pyramidal tracts, in the posterior external columns and the central two-thirds of the postero-median columns.

Cervical region, showing recent degeneration. (Marchi).

The posterior root-zones were diseased slightly; the anterior roots slightly involved, but the posterior roots remained free.

Carmin stain.—The pia was very much hypertrophied and contained many vessels whose walls were greatly thickened. Many of them were filled with blood cells. This change was uniform throughout the whole extent of the cord. The infoldings of the pia into the cord were more numerous than normal, and were thickened and the seat of round-celled infiltration. Numerous blood vessels, whose walls were thickened and which were filled with blood corpuscles could be observed. In the lower cervical segment this process was more intense and especially at that part around the lateral and posterior columns. The change in the pia was less pronounced in the dorsal, lumbar and sacral levels.

The branches of the anterior median artery were thickened and in many places distended. This change was not, however, confined to these arteries but could be found in the posterior median artery and indeed in the entire vascular system of the cord.

Lumbar, combined sclerosis. (Weigert-Pal).

In the direct pyramidal tracts there was an increase in the number of vessels. Some were obliterated, some had thickened walls, some seemed to be of recent formation. The signs of sclerotic change were very marked. The cord was traversed by bands of connective tissue forming trabeculae. Of the spaces so formed, some were empty, but many were filled with compound granular cells and quite frequently with degenerated nerve-fibers. Surrounding these intensely degenerated areas were fibers showing more recent change and among them a number of healthy ones. Many were seen with enormously swollen axis cylinders with granular material around a few.

There were many areas of granular accumulations in the midst of which shriveled axis cylinders could be observed.

A similar condition was noted in the lateral tracts.

In the center of the most intense change fibrous tissue and compound granular cells alone were seen, except in very rare instances when a few fairly healthy fibers persisted. Surrounding this sclerotic area there was a granular layer from which appeared to be crystallizing compound granular cells. Very few fibers were seen, those that persisted presenting some stage of degeneration. Then, receding from the center of the disease, more and more healthy fibers were visible with many granular cells, among which the blood vessels showed the same change as above described. In the white matter were found many capillaries distended with red blood cells. The ganglia cells had suffered considerable change. A number was still normal, but often the nucleus was elongated, with irregular contour and sometimes scarcely visible at all. The cell itself in such cases was rounded and shorn of its prolongations. No hemorrhage could be found. Many of the blood vessels appeared to be old and the walls thickened, with increase of nuclei, while others seemed to be of more recent origin.

In the middle dorsal region the sclerosis was more intense. The bands of fibrous tissues were thicker, the spaces larger. In other respects the change was similar to that in the cervical region, except that there were obliterated blood vessels in the midst of the intensely degenerated areas. In the gray matter there was the same vascular change as found in the cervical region, but it was more

Middle and lower thoracic regions, showing acute degeneration. (Marchi).

intense. Obliterated blood vessels were visible. The ganglion cells were more intensely affected, many of them having undergone profound alteration. It was difficult now to find a cell with prolongations persisting, or to make out the nucleus. Nearly all were rounded and had lost their characteristic shape. One cell was seen in which the nucleus had undergone vacuolization, and another where the entire cell had suffered a similar change. Some had suffered vitreous degeneration. The central canal was choked with granular cells.

The lower dorsal cord.—The gray matter had suffered intense change. There was scarcely a ganglion cell which was entirely healthy. Many capillaries were seen, all distended with red blood cells. There were still no hemorrhages visible. The lateral columns were the seat of a change similar to that described above. Bands of fibrous tissue traversed the affected area and formed spaces which were filled with granular cells. The process already described existed, but it was more intense. In the posterior columns the amount of sclerotic tissue, on the whole, was less than that which was seen in the lateral columns. In the midst of the most intense disease there was a total absence of anything resembling nerve tissue.

Lumbar cord.—The anterior portion, adjoining the median fissure showed a moderate increase in the connective tissue. In the lateral columns, correspond-

ing to the seat of change in the upper levels, there were a number of fibers in which the axis cylinders were swollen and a slight increase of connective tissue was perceptible. In the gray matter there was still evidence of considerable vascular change; numerous capillaries were seen, not more however than in any other level, while the evidence of old vascular change was less apparent. The ganglion cells were mostly exempt from disease; but a few had lost their prolongations, were rounded and exhibited an irregularity in the contour of the nucleus, and very rarely showed vacuolization.

To sum up the pathologic findings in this case, there was a sclerosis involving the direct pyramidal tracts, Gowers' columns, the crossed pyramidal and direct cerebellar tracts, the columns of Goll and Burdach, Clarke's columns, and showing involvement of the gray matter and the posterior roots; a sclerosis which was not entirely systemic, but crept over the limits of the several tracts and tended at certain levels to become quite diffuse. The degeneration was most profound in the middle and lower dorsal segments, becoming less intense in the cervical and still less in the lumbar segments.

The disease involved the lateral and posterior portions of the spinal cord to a greater degree than elsewhere. The gray matter was most severely affected in the cervical region, the posterior roots and the reflex collaterals in the lumbar region. Beside the old sclerotic change there was visible an acute process which was especially noticeable about the areas showing the most intense chronic change.

It is interesting to note that the root zones did not appear to be greatly involved in the chronic process as shown by the Pal staining. It would be difficult to explain the absence of knee jerks late in the disease on the strength of the findings shown by this method. But by the Marchi process, these zones as well as the reflex collaterals show extensive involvement, easily accounting for the final disappearance of the knee jerks.

The acute process was located around the seat of the old degeneration and extended the whole length of the cord. In the midst of the areas of advanced chronic degeneration there were seen only a few acutely degenerated fibers, but this was because but few fibers remained exempt from the chronic process. Our specimens did not bear out the diagnosis made during life but led us to consider the case as one of those which have been described by Rothman as "primary combined system disease." It is true that the disease was most intense in the dorsal region, suggesting the possibility of a chronic diffuse process in this district with resulting ascending and descending degeneration. A study, however, of the distribution of the sclerosis above, in the cervical, and below in the lumbar and sacral regions, does not disclose the presence of ascending and descending degeneration. In the upper dorsal and cervical regions the degeneration in the posterior columns was diffuse and lacked the characteristic distribution of ascending degeneration in these tracts. Moreover, the pyramidal tracts at these levels were extensively diseased. In the lumbar region the degeneration in the posterior columns was quite extensive and not limited to the areas of descending degeneration which follow transverse lesions in the dorsal cord. The distribution of the lesions corresponded quite accurately to that of primary combined sclerosis. It was most intense in the

lower dorsal region; less in the cervical and least in the lumbar region. This same distribution of the disease was well illustrated in a case reported by one of us in the *Journal of Nervous and Mental Diseases*, November, 1896. In that as well as in the present case there was a small strip in the posterior columns, round the posterior horns, which had escaped degeneration at all levels. In the present case the acute process, however, had attacked this area quite intensely, especially in the dorsal cord. It is interesting to decide what significance the presence of the acute process possessed. That it had the same distribution as the old process and bordered on it so closely would suggest an intimate relation between the two—was it an acute exacerbation of a chronic process?

A review of the literature of this subject leads us to think that many of the cases described as combined sclerosis do not agree either clinically or pathologically. In some, the spastic symptoms seem to predominate—in others, the ataxic symptoms. Arnold,¹ in 1892, divided the combined sclerosis into the spastic and paraplegic forms. In 1878 Westphal² called attention to the variability of the symptoms and conditions, which Rothman has since emphasized. Kahler and Pick³, in 1878, were the first to observe the symptoms of combined system disease, which they described as follows: "Combined system disease in the spinal cord is one in which numerous systems are diseased at the same time and from the same cause."

Marie's⁴ classification is as follows:

1. True systemic sclerosis; *a*, typical tabetic disease of the posterior columns with degeneration of the lateral columns in general paralysis; *b*, disease of Goll's and Burdach's with the cerebellar tracts.

2. Systemic sclerosis of the posterior tracts with diffuse myelitis of the lateral tracts due to leptomeningitis.

3. Diffuse myelitis with ascending and descending degeneration.

4. Diffuse myelitis of pseudo-systemic character.

Ballet and Minor⁵ (*Archiv. de Neurol.*, Vol. VII, 1884) divide the combined sclerosis of lateral and posterior columns into, 1, diffuse sclerosis of pseudo-systemic character; 2, typical tabes with disease of the direct cerebellar tracts; 3, tabes with leptomeningitis, the inflammation attacking the lateral tract; 4, interstitial diffuse myelitis, particularly of the thoracic cord, with ascending and descending degeneration; 5, true combined system disease.

Rothman⁶ refers to six groups of combined sclerosis: 1, Friedreich's disease; 2, cases of old tabes in which there is involvement of the lateral tracts; 3, spastic spinal paralysis with primary degeneration of the lateral tracts and secondary degeneration of the posterior columns. He cites as examples the cases of Westphal,⁷ Reymond,⁸ and Popoff,⁹ Strümpell¹⁰ and Dana;¹¹ 4, spastic spinal paralysis with disease of the pyramidal and cerebellar tracts with slight involvement of ganglion cells in the anterior horns, the posterior columns remaining normal. Minkowski's (*Deutsch. Arch. f.*

Klin. Med., 1884) and Münzer's cases (*Wien. Klin. Woch.*, 1892), are cited as examples of this disease. Rothman believes that these cases belong to the last group, being in the early stages of the disease; 5, combined sclerosis of the lateral and posterior tracts in progressive paralysis; 6, a group which he has termed "primary combined column disease," having collected twenty-seven illustrative cases. His conclusions from the study of these are: 1, that primary combined system disease must be considered a disease by itself; 2, that clinically it is distinguished by symptoms pointing to the disease of the posterior and lateral tracts; 3, that the patellar reflexes remain either present until death or disappear in the last stages of the disease; 4, that the pupillary reaction is in almost all the cases present; 5, that usually the process first attacks the lower extremities and extends later to the upper extremities; 6, that the disease runs a moderately rapid course, extending not over three years. In the spinal cord there is degeneration of the posterior tracts, the posterior roots remaining almost always free; there is a moderate involvement of the posterior root zones and crossed pyramidal, and usually also of the direct pyramidal and direct cerebellar tracts. An irregular slight degeneration of the remaining parts of the anterior lateral tracts was present. In a great number of cases there is disease of the gray substance. The cause of the process is best found in the primary affection of the gray substance. Concussion and pernicious anemia are particularly to be thought of in the etiology, while syphilis seldom plays any part. The cases of old tabes with degeneration of the lateral tracts in the last stages and of spastic paralysis with degeneration of the crossed pyramidal tracts and secondary inflammation of the columns of Goll and the direct cerebellar tracts, are to be differentiated from this disease.

Leyden (*Zeitsch. f. klin. Med.*, 1892, p. 23) has divided chronic disease of the spinal cord as follows: 1, chronic myelitis with sclerosis of the spinal cord: *a*, circumscribed form; *b*, disseminated form; *c*, diffuse form; 2, systemic disease: *a*, tabes dorsalis; *b*, the spinal form of progressive muscular atrophy and bulbar paralysis (type-Aran-Duchenne); 3, Friedreich's disease; and 4, syringomyelia.

We are inclined to believe that the cases diagnosed as chronic myelitis are often, if not always, examples of combined system disease, as Oppenheim¹² claimed. It was his belief that many of the cases reported as myelitis by Leyden must now be considered as cases of combined sclerosis.

The change in the spinal cord in our case, demonstrated by the carmin sections, showed enormous involvement everywhere of the blood vessels, especially in the gray matter. It will be remembered that the blood vessel walls were thickened; in some the lumen was obliterated, and in places there were numerous capillaries of recent formation. There was also some round-celled infiltration in the membrane and gray matter, though this was not very marked. In many places the appearance suggested an inflammatory change. There was, besides degeneration of the nerve tissue, increase in the connective tissue. We believe the process was vascular in origin, thus agreeing with the opinion of Ballet, Minor and Marie, and contrary to the opinion of Rothman, who argued that the primary seat of the disease was in the ganglion cells of the anterior horns. The process

seems to be a rapid one. According to Rothman, the duration of the disease is never over three years. In the case reported in the *Journal of Nervous and Mental Diseases*, above referred to, the patient died three years after the onset of the disease, and in the present case the duration was a little over two years.

The possibility occurs to us that the cases collected by Rothman, those described by Gowers¹³ as ataxic paraplegia; a small group of cases reported by Westphal, Reymond, Popoff and Strümpell in which first the lateral and secondly the posterior columns appeared involved, belong to the same class of spinal degeneration. On the other hand, Gowers claims that both the nerve elements and interstitial tissue may be involved, and that when the process extends beyond the tracts especially diseased, and symptoms such as girdle pains and loss of sensation are present, the cases should be classed as examples of chronic myelitis.

GASTROSTOMY—PRESENTATION OF ILLUSTRATIVE CASE.

Read before the Illinois State Medical Society, held at East St. Louis, May 19-20, 1897.

BY J. A. BAUGHMAN, M.D.

NEOGA, ILL.

Mrs. R. E., 20 years of age, in August, 1895, swallowed an indefinite quantity of a solution of potassium hydrate, commonly known as concentrated lye, of uncertain strength. Whether any of the chemical reached the stomach is not known, but its escharotic effect was markedly exerted in the esophagus. I did not see the case for some weeks after the accident and am unable to say what, if any, constitutional effects the drug produced. The attending physician treated the case by quieting pain, giving demulcent drinks and liquid food. No attempt was made to preserve the lumen of the esophagus by the systematic passage of bougies during the time cicatricial contraction was taking place. While such a procedure is advocated in many of our text-books it is of doubtful utility; for gradually and persistently stenosis and atresia succeed each other.

In December, 1895 the case was referred to me, as one of stenosis of the esophagus with threatened starvation. What would be more natural than to attempt the passage of an esophageal dilator. I could pass it no further than ten inches below the edge of the superior incisor teeth. I tried bougies and tubes of different caliber and rigidity without avail, as we sometimes do in urethral stricture. I tried the insertion of two instruments at the same time, thinking one might occupy a false pocket, thus giving direction to the other through the stricture. Foiled in this I used some degree of force with the instrument. I had no way of measuring the degree of pressure, simply trusting to touch and judgment; but in traumatic contraction of the esophagus the walls of the organ are greatly thickened and there is much less liability of rupturing it than in cancerous contraction, the most common form of stricture in this locality. The close relation of the esophagus with important organs would make perforation of its walls an extremely dangerous accident. I despaired in opening the canal, and had I succeeded in passing a bougie, it is very doubtful if dilatation would have accomplished any permanent benefit.

¹² Oppenheim: *Berliner Klin. Wochens.*, 1891, p. 761.

¹³ Gowers: *Diseases of the Nervous System*, 1892.

My patient was rapidly starving. I explained gastrostomy to her. This operation was first performed by Sédillot forty-eight years ago, but the first success was scored by Sidney Jones, of England, as late as 1874. My patient submitted to operation in January 1896.

In cases of this kind, where stenosis is due to an escharotic, an operation, if not a duty, is much more commendable than in cancerous stricture, and even in malignant contraction I believe the operation should be done.

I performed gastrostomy by the method known as Von Hacker's, by some authors credited to Howse. This method consists of making the opening in the abdominal wall at a point about three inches below the ensiform cartilage and a little to the left of the median line. The incision in the skin was two and a half inches and that through the peritoneum one and a half inches long and almost vertical in direction.

The two principal reasons for selecting this point for the opening, are its relation to the stomach and that we may go through the body of the rectus abdominis muscle, hoping to utilize the muscular fibers of this body as a sphincter to our artificial os. In my case I was compelled to go a little lower than desirable on account of the liver and a transverse tendinous intersection in the muscle that would have afforded very few muscular fibers.

The transverse colon first presented, this was pushed down, the stomach was seized with forceps, drawn into the wound in such a manner as to avoid tension at the cardiac and pyloric ends. It was found very clean and empty and somewhat contracted. A hairlip pin was passed through the upper fold of the organ both to hold it and serve as a guide in making the gastric incision a day or two later. This pin is a very valuable part of the operation for the reason that in a few hours the wall of the stomach and the whole bottom of the wound lose all their former appearance, only showing a mass of lymph and other inflammatory products that are very confusing. The peritoneal surfaces of the stomach and abdominal wall were sewn together with a continuous silk suture. I consider this a mistake as it is next to impossible to remove the thread a few days later, so completely is it buried and held by the exuded lymph. An interrupted suture with long free ends or an absorbable animal suture would be greatly preferable.

The suture was passed through only the serous and muscular coats of the stomach and an area of the sac about the size of the thumb nail left exposed. The opening into the stomach was made three days after the primary operation. This is easily and painlessly done by first dropping a few minims of a solution of cocaine into the bottom of the wound and then, in about five minutes, with an ordinary cataract knife cutting out the hairlip pin which was previously passed entirely through the wall of the stomach. Deferring the secondary operation was for the purpose of admitting of the formation of inflammatory adhesions between the stomach and abdominal wall at the seat of the operation, thus isolating the gastric opening from the general peritoneal cavity and preventing leakage into the latter. Statistics show that the operation in two steps, thirty-six to seventy-two hours apart, is a great advantage in avoiding peritonitis and death. The patient's recovery was uneventful. There was no elevation of temperature during convalescence.

Our first method of introducing food into the stomach was by the introduction into the fistula of a soft catheter. To the patient this method of feeding was very unsatisfactory on account of the pain produced when inserting the instrument. She insisted that the tube be left in the opening from one feeding to another; and being a person of strong will she had much her own way about it.

I then had made for her a tube of sterling silver about an inch long and three-eighths of an inch in diameter with a retaining flange on one end and a cap or lid on the other. This tube was inserted and retained by the flange on the other end and elastic belt.

I have tried many times to open the esophagus, both from below through the gastric fistula and from above, but have long since ceased my attempts, as we now have a complete atresia of the esophagus under the middle of the sternum, not a drop of fluid having passed through the esophagus for sixteen months. With an ordinary bicycle pump we constructed a good strong syringe and with this she forces custards, mashed potatoes, crushed fruits, etc., into the stomach and keeps herself nourished well enough to be able to suckle a robust baby, to which she gave birth about eleven months after the operation. The patient goes about her household duties and shopping much as she did prior to the injury.

I can not defend leaving the tube permanently in the opening with any good reason, except that the patient demands it. I am perfectly aware that the instrument is liable to cause atrophy of the tissues in juxtaposition to it, and possibly an ulceration of the stomach; but as there are two parties concerned in the matter so are there two opinions to be respected.

Thus far there has been very little leakage of the gastric juice and very little irritation of the margins of the opening. If there were soreness alkaline washes and stable unguents would be in order.

I believe if I had another case to operate upon I would adopt a different method. While this has so far been practically a success, theoretically we reason that a valve method, such for example as practiced by Albert, would be better. Yet in cases where we hope to subsequently do retrograde dilatation, the mode selected in this case is no doubt the best.

I have been very anxious that my patient masticate her food and economize the saliva, but in the last year she has practically had no saliva in the stomach. Chewing the food causes a distressing spasm of the pharyngeal muscles and she absolutely refuses to try mastication. To check the secretion of saliva she has constantly taken belladonna. The size of the dose does not need to be increased. She has consumed about a pound of the fluid extract within the last year. Our text-books teach that an absence of saliva in the process of digestion and nutrition can not long be endured. So far my case does not verify this statement, yet I have apprehensions of trouble in the future.

NOTE.—April 5, 1898.—There has been no material change in the case since this report was given.

The Watch-Spring and the Gigil Wire Saw.—Watch-springs have an eye in the outer end, and their extreme flexibility, without lateral motion, adapts them ideally for a carrier of the wire saw, Lauenstein asserts in the *Cbl. f. Chir.*, February 26; *vide JOURNAL*, March 5, page 558.

ANTITOXINS.

Read before the Michigan Academy of Science at Ann Arbor, Mich.,
April, 1, 1897.

BY E. MARK HOUGHTON, M.D.
DETROIT, MICH.

As we note the army of workers in the field of bacteriology, and the vast amount written on the subject, we can hardly realize that it has been scarcely twenty years since the germ was first demonstrated as the cause of a disease, and less than three years since Behring and Roux published perfected methods for preparing and administering diphtheria antitoxin. During this short period of discovery, recognized but unexplained truths have been elucidated, and many new facts have been brought to light. Many of the facts of immunity have been known since prehistoric ages, but prevailing theories regarding these questions were at fault; consequently, clinical interpretations and treatment have been fallacious.

Before studying the antitoxins, it will be well to take a brief historical survey of the knowledge already acquired regarding the facts of immunity and the theories put forth to explain these facts. Pasteur in 1880 began his studies on chicken cholera, and reached the conclusion that it would be possible by a process of vaccination, "for man to eradicate every contagious disease from off the face of the earth," and, from his researches, he formulated the theory, that where a susceptible animal was treated with attenuated cultures, something which was necessary for the development of the disease germ in the animal body was destroyed. The exhaustion theory, as the hypothesis of Pasteur was called, almost as soon as announced, was disputed by Chauveau, who believed that bacteria ceased to grow, and finally died in culture flasks, and that men and animals recovered from bacterial infection when the excretory products of the disease germs had accumulated in sufficient quantities to destroy the invading microbes, in the same manner as higher plants and animals are destroyed by their own excreta. Immunity, it was explained, was due to the very slow elimination of these bacterial products from the organism of the subject. This theory was accepted by Koch to explain the curative results of tuberculin. Klebs and others endeavored to find similar remedies for other of the infectious diseases, but today we repudiate the explanation although the facts hold true. These investigations paved the way for the discovery by Behring and Roux, that something is formed by the tissues of the animal body, which enables the animal to withstand the invasion of pathogenic bacteria, or destroys them after they have gained an entrance; and that the immunity of one animal can be borrowed and conferred upon another. The scientific world was awakened; more light was needed; the dawn of a new era in medicine showed forth; ideas and experiments took a more definite form; new facts opened the way for long series of discoveries. Ehrlich succeeded in immunizing animals against the most potent vegetable poisons, and in obtaining from the blood of the treated animals a protecting substance, which, when administered to other animals, protected them against harm from many times the fatal dose of the poisons; he also devised a method for quantitatively estimating the value of the protecting substance. The commonly observed fact that nursing babes are much less susceptible to microbic disease than are bottle-fed infants was satisfactorily accounted for when it was found that the young of animals immune

to a certain disease were much less susceptible to that disease than the young of unprotected animals, and many of the common facts of natural and acquired immunity were satisfactorily explained.

The crisis of the revolt against old ideas occurred, when in August 1894, at the World's Congress of Hygiene, at Buda-Pesth, Behring and Roux convinced many a doubting Thomas, that diphtheria antitoxin was nature's remedy for treating that dread disease. In the two years and over that have elapsed since then the field has been broadened, the army of workers has greatly multiplied, exhaustive researches have been undertaken and accomplished, new antitoxins have been discovered and much capital has been enlisted to supply these remedies at a reasonable price. With the exception of anti-diphtheritic serum, and perhaps one or two others, all this class of remedies yet remain in the experimental stage. Probably many of them will be greatly modified, and some rejected, before medical opinion becomes settled as to the value and limitations of serum therapy. Definite conclusions can not yet be drawn from the immense amount of experimental evidence, often conflicting which has already been submitted regarding the exact chemic nature of the bacterial and other products employed in treating animals, the resulting antitoxins, and the biologic factors concerned.

We will review the various antitoxins, calling attention to some of the salient points connected with their production.

Anti-diphtheritic serum.—Since this antitoxin is of chief importance, and will serve as a type of the methods of producing the others, a somewhat detailed description will be given.

To Klebs belongs the honor of first pointing out the specific germ of diphtheria. Löffler soon confirmed his work, and concluded that this specific germ was always present in true cases of diphtheria.

Many of the most important boards of health in this country and in foreign lands are now taking the results of bacteriologic examination, as the main criterion in deciding whether a given case of sore throat is diphtheria. Even the smaller towns and country hamlets are asking for assistance. Sooner or later every physician, who claims to be up with the times, will be obliged to know how to make bacteriologic examinations, not only of diphtheria but of many other diseases.

In preparing the serum it is of paramount importance to have virulent cultures from which to obtain the toxins to be used in the immunizing process. Most of the cultures grown from specimens taken from the throats of patients are mixed with other forms of bacteria and must be purified by appropriate methods. When pure, or when properly purified, these cultures must be tested for virulency on the guinea pig; if they prove rapidly fatal to these animals when injected in small quantities it will not be necessary to exalt their virulency by passing them through a series of animals, as must be done when the toxic properties of the cultures are very slight. It has been found that the best methods of keeping the cultures in a high state of cultivation is to transplant them daily into fresh bouillon possessing an exact degree of alkalinity. In this way very luxuriant cultures are obtained, which remain virulent for many months. The tested and approved pure cultures of bacteria are planted in large flasks of beef bouillon, which are placed in the incubator and allowed to remain about

seven days, when they are taken out and examined microscopically to make sure that no foreign bacteria are present; then a small per cent. of carbolic acid, or trikresol, is added to prevent the development of other germs which have accidentally gained access to the flask. The approved culture is finally filtered with strong pressure through sterilized porcelain filters, which take out all bacteria present, leaving a clear brown, or straw-colored (depending on the color of the bouillon used) transparent fluid, which is called diphtheria toxin; the specific poison of the germ, however, represents but a very minute portion of this fluid, which contains approximately 98 per cent. water, besides salts, peptones, etc. The virulency of this toxin must be determined before it is used to immunize the horses. Its poisonous properties may be so great that 1/50 to 1/10 of a drop will suffice to kill a half-grown guinea pig. Indeed, not long since, a healthy 1200 pound horse under the writer's care died with the symptoms of diphtheritic paralysis from the effects of an initial injection of only two drops of the fluid. Two years ago it was only possible to produce after many months a toxin 1/50 as strong as can be produced in one week's time at present. Park and Williams find that this difference in the strength of toxins is due to the difference in the alkalinity of the bouillon in which the germs are grown. They recommend that the bouillon should be so thoroughly alkaline as to require 7 c.c. normal acid to the liter to make it neutral to litmus. Phenolphthalein is, however, a much more reliable indicator than litmus for making the titrations.

The greatest care should be exercised in selecting the horses that are to be immunized. Only young, healthy animals should be used and be carefully inspected by a competent veterinarian, tested for tuberculosis and glanders, and kept under observation for several days before they are accepted.

Many methods have been employed, at the suggestion of different investigators, for producing immunity in these animals.

Behring and Roux both use practically the same method—the one generally employed at the present time. Small initial subcutaneous injections of the toxin are made: 1/10 c.c. of the strong toxin now in use diluted with sterile physiologic saline solution to 1 c.c. is quite sufficient. The degree of reaction is very variable in different horses. Some will show almost no local or general reaction, while others in apparently as good condition are rapidly prostrated with even the smallest injections. The temperature may be 5 or even 6 degrees above normal and marked local swelling occur. In the writer's experience, if the temperature rises more than 4.5 degrees the horse will surely die, either from the primary injection or subsequently if treated farther, unless antitoxin is administered. This fact suggested to me the possibility of producing immunity in such animals by combating the marked symptoms with injections of antitoxin. Pawlowsky and Maksuton report, since my experiments began, that they have succeeded in immunizing horses in forty to fifty days by first treating them with antitoxin and then with toxin. It is too early to say what the outcome of my experiments will be, but I have been able to save the lives of several animals with antitoxin and they are now standing the treatment with the toxins very satisfactorily. The great difference in reaction to the toxin on the part of different horses has been shown by Bolton to be prob-

ably due to the fact that the blood serum of some unimmunized horses contains antitoxic substances. Among other animals a similar variation in resistance to other poisons is observed. The intravenous method of injecting the toxin has been employed quite extensively, with varying results. The local and general disturbance, contrary to what might be expected, is much slighter when the toxin is introduced directly into the circulation than when injected subcutaneously.

Klein found that by beginning with a small injection of attenuated culture of diphtheria germs and gradually increasing the quantity and virulency of the germs at the subsequent injections, the animal is able to take large quantities of the most virulent cultures in three or four weeks time. This method of producing immunity is quicker and less dangerous to the horses than the method of Behring, but it has been found impossible, thereby, to produce a very strong serum, even after long continued treatment.

Wassermann has recently shown that if an animal be immunized with virulent cultures of bacillus pyocyaneus its blood will acquire strong bactericidal but weak antitoxic properties. On the other hand, if the animal be immunized with the toxins instead of with the germs the resulting serum has both germicidal and antitoxic properties in marked degree.

By all of these methods strong immunity can be produced. It may be that a combination of methods will be found ultimately to be more satisfactory than any one method alone. Horses, as human beings, have their own individual characteristics, that must be taken into consideration in order that the best results may be produced. Occasionally a horse will, while under treatment, show all the typical symptoms of post-diphtheritic paralysis, some even regurgitate their food. Such cases recover very slowly, or may suddenly die of heart failure, as do so many human patients. The horses that do take the treatment satisfactorily become sleek and well nourished. One horse under the writer's care gained over 300 pounds while under treatment. Exercise, sunshine and fresh air—in fact the best hygienic conditions—are all essential factors.

The amount of toxin and the length of treatment necessary to immunize animals so they will produce antitoxins of a given strength vary within wide limits. Some horses will produce a strong antitoxin for a time, and then, notwithstanding the fact that we can inject very large and increasing quantities of toxin, the serum will become much weaker. To illustrate: one horse under my observation shows very little disturbance from an injection of 1200 c.c. of a strong toxin, enough to kill several thousand unimmunized horses, yet its serum is not over one-half as strong as it was a year ago, and not nearly so strong as the serum obtained from a horse which shows marked reaction after much smaller doses. Behring has noted that a horse in the course of treatment may become highly susceptible to the toxin and yet produce very strong serum. The variabilities and difficulties connected with the production of antitoxin are well-nigh distracting.

After the animals have been treated for a considerable time, and are able to resist large quantities of the toxins, test quantities of blood are drawn from the jugular vein, under aseptic and antiseptic conditions, into sterilized flasks, or tubes, and placed in the refrigerator. After some hours the clot contracts and squeezes out the clear, straw-colored serum,

which contains the antitoxin. This serum is drawn from the flasks, or tubes, into a sterilized container, some preservative, trikresol, camphor, carbolic acid, etc., added, allowed to stand some time, and is then passed through sterilized filters into sterilized containers.

The antitoxic value of the serum must now be determined, before it is finally filled into the bottles, or bulbs, and finished for marketing. Several methods of standardizing the serum have been proposed, but that of Behring and Ehrlich has been most generally accepted in this country. It is carried out as follows:

Half-grown guinea pigs are the animals employed. Ten times the fatal dose of diphtheria toxin is mixed with variable quantities of the serum containing the antitoxin, then injected subcutaneously into the animals. To illustrate: Suppose we find that 5 milligrammes of a given toxin is the fatal dose for the test animals; in testing, 50 milligrammes of the toxin are measured out, mixed with, say, 1 milligramme of the serum containing the antitoxin, and injected into pig No. 1. Pig No. 2 receives a like amount of the toxin, mixed with $\frac{1}{2}$ milligramme of the serum. After a few days we find that pig No. 1 is well and healthy, in fact has never been sick, while pig No. 2 died in forty-eight hours. We would say that 1 milligramme of the serum, $\frac{1}{1000}$ c.c., is sufficient to protect a guinea pig against 50 milligrammes of toxin ($\frac{1}{2}$ c.c.) and that each cubic centimeter of the serum contains 100 antitoxic units—an antitoxic unit being ten times the quantity of serum necessary to protect a medium-sized pig against ten times the fatal dose of diphtheria toxin. The definition of what constitutes an antitoxic unit has been so differently stated by medical writers that much confusion has arisen as to what is meant by so many units strength. Two years ago the strongest serums on the market contained only about 100 units per c.c. At the present time we are able to make serums five times as strong.

Finally, the completed and tested antitoxin is filled into sterilized containers, and is ready for distribution. Some firms prefer to put up several grades of serum, using containers holding from 2 to 20 c.c. of fluid. Others believe it is better to keep the average dose as small as possible, and list the number of units, irrespective of the amount of fluid, never allowing the latter to exceed 5 c.c.

The question is often asked, "How long will serum keep?" If properly prepared it should keep indefinitely, in the sense of putrefying; but undoubtedly, like other complex albuminous bodies, it begins to deteriorate, or lose strength, as soon as prepared. This loss in strength, however, takes place very slowly when the serum is kept in a cool, dark place. Manufacturers generally add sufficient excess of serum so that the package will contain the number of units claimed on the label at the end of six months.

Vaccine.—Vaccine, not because of its time-honored place as a prophylactic agent against smallpox, but because of the recent work of Beclère and others, deserves mention. Some time after the pustules have disappeared from vaccinated heifers their serum shows decided immunizing properties, proved by the fact that when it is injected into fresh animals and vaccination immediately performed, fewer pustules develop, those that do appear are rudimentary or abortive, and the lymph obtained is very inactive.

If, on the other hand, vaccine virus is injected subcutaneously into the animal just before vaccination, the vaccine lesions remain unmodified. However, if the injections of vaccine lymph precede the vaccination several days, slight immunity is conferred. If the serum is injected within forty-eight hours after the vaccination, little or no reaction is manifest. Consequently we may say that the serum, in contrast with the lymph, possesses not only an immunizing property, but a curative one also. Whether the serum from vaccinated animals will be of value as a preventive, or in the treatment of smallpox, remains yet to be demonstrated.

Anti-venomous serum.—Sewall (1887) succeeded in immunizing pigeons against rattlesnake poison by administering gradually increasing quantities of the venom, so that finally the birds could withstand seven times the fatal dose. This immunity lasted for several months.

Fraser (1895) found, from very extended experiments with venom from the cobra, rattlesnake, and many other poisonous snakes, that animals immunized against one venom were immunized against the other venoms also—that neither local nor general reaction follow inoculation with many times the fatal dose. Some of the animals gained in flesh and seemed benefited by the treatment. Calmette and his co-workers in the Pasteur Institute confirm Fraser's work, and have added many new facts bearing on the question. The protection of man from the bites of serpents, by artificial treatment with their poison, has been known and practiced for ages, by the snake charmers of India. How well they have kept their secret need not be told. The importance of this work can be appreciated from the fact that reports show that every year over 20,000 people die, in India alone, from the bites of venomous snakes.

Abrin and ricin antitoxin.—Ehrlich succeeded (1891) in immunizing, and obtained a strong antitoxin by feeding larger and larger doses of the poisons, ricin (from the castor bean) and abrin (jequirity bean). These antitoxins are specific in the true sense, since the one antitoxin does not protect an animal from the poisonous effects of the other. These results are of great importance from a scientific point of view, but of little practical importance to the physician, although the abrin poison may be of some use to ophthalmologists.

Calmette, in concluding his recent researches on toxins not containing microbes, abrin, ricin, snake venom, etc., says: "The antitoxic function is independent of immunity, since it can exist, although the antitoxic function does not manifest itself. The hen and the tortoise resist large doses of these poisons, but their serum is entirely inactive against abrin poison. Natural and acquired immunity are the result of a special property of the cell."

Anti-tetanic serum (lockjaw).—Kitasato (1889) showed that tetanus was due to a special germ, which, if injected into susceptible animals produced typical symptoms of tetanus; this germ could be obtained from the body of a person dying from the disease. Shortly afterward he succeeded in immunizing rabbits, whose blood serum was found to contain antitoxic substances. These results were confirmed by Tizzoni and Cattani in 1891. Behring and others, in 1892, detailed a method for immunizing horses and obtaining their serum, which was used experimentally on man. The same year Brieger and Ehrlich immunized

goats and found that the protecting substance was present, not only in the blood of the animal but also in its milk. Later he obtained the antitoxin in an impure form as a dry powder from the milk. The potency of the poison of this germ, even in an impure form, can be scarcely realized, a few grains being sufficient to exterminate a whole army of men. Of the greatest importance to the physician was the demonstration that it requires thousands of times as much antitoxin to cure an animal, after the symptoms have developed, as it does to prevent the development of the disease by giving antitoxin soon after the animal is infected; hence the necessity of prophylactic injections in cases of suspicious wounds. This serum is dispensed as a fluid, or in a dry form.

Anti-tubercle serum.—This serum is prepared in the usual way, from the blood of horses that have been immunized against attenuated cultures of the tubercle germ, or their poisonous product (tuberculin). Maragliano and Paquin have made considerable claims for this serum as a curative agent, but at present I believe it should be regarded merely as an experimental remedy.

Anti-streptococcic serum.—It is now generally assumed that erysipelas, puerperal fever, and certain septicemias are due to streptococci of the same or closely related species, and that these germs often attack the weakened tissues and complicate such diseases as scarlatina, diphtheria, tuberculosis, etc. It was early perceived that a serum efficacious against these germs, or their toxins, would have a wide field of usefulness. Marmorek first succeeded in producing such a serum, but his results thus far have not been confirmed, either in this country or in Europe. However, there is quite a demand for the preparation in this country; whether it will prove of value remains to be determined.

Anti-typhoid serum has been prepared, but thus far the results are not very satisfactory.

Anti-bubonic serum is perhaps the latest and most important addition to serum therapy. The results obtained by Kitasato, Yersin and others from the use of this serum are very encouraging. It is prepared from the blood of horses immunized by some one of the methods already mentioned.

Anti-syphilitic serum has been tried, but at present the prospects of success are very meagre.

Anti-rabic, anti-choleric, and other serums have been prepared, but it is not necessary to mention them here, since they are prepared along the same general lines as the others.

We find, briefly, that immunity can be conferred against a great variety of substances of animal, vegetable and bacterial origin. This immunity may be produced by feeding the poison, or by injecting it subcutaneously or intra-venously: it can be borrowed from one animal and loaned to another to aid the tissues in their efforts to prevent the entrance of disease organisms, or to destroy such organisms after they have gained access to the citadel of life. The immunizing substance is found to be present in varying quantities in the different fluids and organs of the animal body. At present we are unable to say where this protecting substance is formed in the animal body. Much of the recent work shows that the white corpuscles have much to do with its production. One of the latest investigators asserts that he has evidence that it is formed in the marrow of the bones.

The great practical importance of antitoxins in the treatment of disease justify the conclusion that rational medicine may justly claim to be one of the most progressive of the sciences.

A METHOD FOR THE QUANTITATIVE ESTIMATION OF INDICAN AND INDIRUBIN IN THE URINE.

BY H. RICHARDSON, M.D.

CLINICAL PATHOLOGIST MOUNT HOPE RETREAT, MARYLAND.

AND E. L. WHITNEY, M.D.

DEMONSTRATOR OF CLINICAL PATHOLOGY AT THE BALTIMORE MEDICAL COLLEGE,
BALTIMORE, MD.

The methods in general use for the detection of indican in the urine are too well known to require recapitulation; they are qualitative and are of little or no value for clinical diagnosis; all are based on the breaking up of the indoxyl sulphate with hydrochloric acid, oxidizing the indoxyl into indigo, dissolving in chloroform, when the blue coloration obtained is utilized to estimate the excess. Errors arise in this method from a variety of causes. If the total quantity of urine passed in the twenty-four hours is small, a deep coloration may be obtained in the test tube, while the total amount may be normal; on the other hand, if the quantity for twenty-four hours is large, little or no coloration may be obtained, and yet the total quantity may be in excess of normal. Another point is the varying difficulty of breaking up the indoxyl; sometimes the mere addition of hydrochloric acid may produce a coloration, at others the color will only appear after standing some time. The various oxidizing agents used, viz., sodium or calcium hypochlorite, hydrogen dioxid, potassium permanganate, etc., will give different results with the same urine. If iodine or salicylic is present, the results are unreliable.

The quantitative estimation by the method of color comparison must necessarily be inaccurate, as no two observers see shades alike, and even the same observer will not always arrive at the same result. Again it is very difficult to oxidize to the exact point, any excess of the reagent bleaching the indigo.

It is evident that if the determination of indican is to be of any use in clinical diagnosis, a more accurate method is required.

The writer's method is based on the precipitation of indigotin by boiling the urine with hydrochloric acid and ferric chlorid, filtering and estimating the nitrogen in the precipitate.

Method.—The urine should first be filtered to remove any mucus that may be present, and if the specimen contains albumin it must also be removed.

Take 500 c.c. of the filtered urine, add excess of hydrochloric acid and ferric chlorid, boil for one hour, cool, filter (preferably with a suction pump), wash well with boiling water, and estimate the nitrogen in the precipitate by the Kjeldahl method. The nitrogen multiplied by 17.9285 will give the amount of potassium indoxyl sulphate, and the nitrogen multiplied by 7.0 will give the amount of sulphuric acid in combination as indoxyl. As indoxyl is often present, not in combination with sulphuric acid, the latter figure is not reliable. If it should be desired to estimate the indirubin separately, the precipitate should be washed with 97 per cent. alcohol, which will dissolve out the indirubin. The alcoholic solution of indirubin is evaporated and the nitrogen estimated by the usual method.

The following are a few results obtained by the authors:

Case of Chronic Mania.—Total quantity of urine passed in twenty-four hours, 1900 c.cm.; specific gravity, 1015; sulphuric acid in conjugate sulphates, 0.1008 per cent.; indican, 0.0125 per cent.; sulphuric acid in indoxyl, 0.0049 per cent. This specimen showed no reaction by the ordinary test.

Case of Melancholia Attonita.—Total quantity of urine in twenty-four hours, 900 c.cm.; specific gravity, 1025; sulphuric acid in conjugate sulphates, 0.0336 per cent.; indican, 0.027609 per cent.; sulphuric acid in indoxyl, 0.01078 per cent. This specimen showed a marked excess by the ordinary test.

Case of Morphin Habit (Convalescent).—Total quantity of urine in twenty-four hours, 1400 c.cm.; specific gravity, 1028; sulphuric acid in conjugate sulphates, 0.042 per cent.; indican, 0.02886 and indirubin 0.01505 per cent., total, 0.04391 per cent.; sulphuric acid in indican, 0.01127 per cent., and in indirubin, 0.00588, total, 0.01715 per cent.

Case of Gastric Cancer.—Total quantity of urine in twenty-four hours, 480 c.cm.; specific gravity, 1018; indican, 0.03513 per cent. Qualitative test showed very marked excess.

The normal amount of indican eliminated in the twenty-four hours is variously given by different writers. Dr. Charles Simon of Baltimore gives 0.0066 as normal, while Allen gives 0.004 to 0.019. As these quantities have been estimated by the color method they are probably below the normal amount, the author's analyses showing that even where no coloration was given by the qualitative test there was a total elimination of 0.0125 per cent., equal to 0.2365 cubic centimeters in the twenty-four hours.

The proportion of indoxyl to the total quantity of conjugate sulphates may, after a sufficient number of estimations have been collected and compared, be of great diagnostic value in gastric and intestinal diseases.

NOTE ON DRY CALCIUM SULPHYDRATE AS A DEPILATORY.

Presented to the Section on Cutaneous Medicine and Surgery, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY ALEMBERT W. BRAYTON, M.D.

INDIANAPOLIS, IND.

Calcium sulphhydrate can be made by heating a granulated mixture of plaster-of-paris (calcium sulphate) with granulated wood charcoal (to take off the oxygen). A high temperature is necessary and it is best obtained by means of gas. A muffler is used, i.e., set in cinders or bone ash and the mixture is heated to redness.

By this method neither sulphuric acid or sulphid of iron is used. The dry, rose-colored or whitish product is applied to the skin in a wetted condition, or it may be put on dry and then wetted. Hydrogen sulphid is given off, which causes a rather foul smell. The substance is perfectly harmless to the skin and may be left on any length of time and does not even irritate abraded surfaces. It is not patented and can be made cheaply.

PRAGTICAL NOTES.

Tereben Glycerin or Tereben Water is warmly recommended in the Russian *Medycyna* for the treatment of infected and gangrenous wounds. They are prepared by mixing and forcing air into the mixture through a rubber bulb and the tube which forms hydrogen dioxid by oxidation of the tereben (7 parts glycerin, 4 parts tereben and 1 part dest. water). Set aside for a few days until a sample of the lower layer gives a deep blue reaction mixed with ether and chromic acid, when it is ready for use. Keep in tightly closed receptacles. The wound is cov-

ered with gauze moistened in the terebenglycerin, an ordinary dressing applied outside.—*Cbl. f. Chir.*, March 5.

Intestine Guard and Holder.—K. Roser describes in the *Cbl. f. Chir.* of March 19 a simple little contrivance which automatically holds the intestines out of the way during an operation without requiring elevation of the pelvis or the assistance of another person, while the field is kept clear for the surgeon to operate with both hands free. It consists of an oval ring of soft elastic wire, 25 cm. long by 10 wide, slipped inside a tricot sheath, tied beyond it at each end. The oval ring is then bent over in the middle forming an elastic saddle-shaped guard which is fitted over the intestines, pushing them back and confining them like a diaphragm and held in place by its gentle pressure against the abdominal walls. Two can sometimes be used to advantage and a mull compress can be interposed if the pressure is feared. The amount of "spring" can be regulated by bending the guard, which is also easily sterilized.

Local Steam Treatment of Suppurating Wounds.—A case of extensive, chronic, subpectoral abscesses and fistula into which a sound could be inserted for 12 cm., consecutive to suppuration of the lymph glands of the axilla, is reported in the *Deu. Med. Woch.* of March 3, interesting on account of the improvement and cure that followed the local application of steam, 53 degrees C., from a distance of half a meter, for fifteen minutes, followed by a fifteen-minute bath of the whole trunk at 27 degrees R., with a final douche, finishing with airoil gauze packed into the fistula. As the writer remarks, we find nothing so good as steam for disinfecting instruments, clothing, etc., and why should it not be equally effective in disinfecting wounds and, by stimulating the circulation, promote healthy granulation?

Localization of the Pains in Inflammation of the Accessory Cavities.—Weil considers the information thus derived quite important in diagnosing, as they are a projection of the inflammation on the surface by the patient. The closer the *locus morbi* to the surface the more distinct and constant the localization of the pains. Fleeting neuralgic pains and disturbances in the nasal passages must be differentiated. The latter can be eliminated by cocaineization. The pain from inflammation of the deeper lying sphenoidal sinus is frequently felt in the back of the head, still oftener in the middle of the brow, between the eyebrows and the frontal eminences. He treats all such affections by irrigating through the natural openings. *Wien. Klin. Woch.*, February 24.

The Sweating Form of the Grip.—Marquic has had occasion to observe seven cases of the grip in adults, distinguished by extremely copious sweats and a marked tendency to the formation of adipose tissue. The cases commenced with bronchial disturbances; some were accompanied by distressing cardiac palpitations, all with constipation, lack of appetite and scantiness of urine. The sweats continued for months and left a neurasthenic condition, which in some cases persisted years. He noted that the sweats and bronchial disturbances alternated, one diminishing as the other increased and *vice versa*. All recovered but one, a young soldier with an evident tuberculous lesion in the right lung. A tuberculous meningitis supervened, rapidly fatal, and as the appearance of the meningitis coincided with the suppression of the sweats under the influence of atropin (one-quarter *mul. per diem*), the friends attributed the death to this medication, which always seemed to produce a general sense of suffocation and uneasiness. The grip toxin evidently affects the sweat-producing centers in this form of the disease.—*Jour. de Méd. de Bordeaux*, February 6.

Treatment of Chronic Intestinal Catarrh with Charged Lime Water.—Professor Jaworski of Cracow reports very favorable results from the use of water charged with carbonic acid, each liter also containing two grams of lime carbonate and two grams of lime

salicylate, in chronic intestinal catarrh with defective appetite, pain and tympanism, also in the diarrhea of consumptives and of the uric diathesis. In the severer cases he combines with it a stronger solution (four grams carbonate and three of the salicylate). Half a glass of the stronger solution is taken an hour before breakfast, and half a glass of the weaker after each meal. Before drinking it the excess of gas should be allowed to escape. When the gastric disturbances are severe, the half glass of the stronger is added to half a glass of boiling water, and taken hot four times a day. As the benefit is felt, the stronger solution is omitted and the weaker continued for a month or two. The effect is astringent and antiseptic, and very few cases of chronic diarrhea have resisted this treatment.—*Semaine Méd.*, February 16.

Comparative Study of Ether and Chloroform in Parturition.—H. Hensen announces that the superiority of ether over chloroform for the narcosis of parturients resides in the fact that while both suppress the action of the abdominal muscles, the effect of the ether rapidly passes away and the uterus resumes its contractions in five to twenty minutes, while the effect of chloroform is felt for a couple of hours, preventing contractions and thus postponing the expulsion of the fetus and favoring hemorrhage from atony of the uterus. His numerous tests with primiparae and others, covering several years, were made with a bulb in the uterus connected with a barometric tube. He found that the energy of the uterine contractions increases progressively till the rupture of the bag of waters, to subside then until after the expulsion of the fetus, when the pressure increases again to reach its highest point, a remarkable phenomenon which may be due to the increase of thickness in the uterine wall at this moment. He found that five milligrams to two centigrams of morphin have no effect upon the contractions of the uterus and of the abdominal muscles.—*Sem. Méd.*, February 26., from *Arch. f. Gyn.*, lv, 1.

Treatment of Psoriasis and Eczema with Systematic Scarifications.—Jacquet has thus treated several hundred cases, but in his report restricts his description to eleven cases followed to date in the last two years. The success has been complete and permanent. The patches disappear without leaving a trace, a fact much appreciated by society women unable to appear *decouletées* previously, and artists whose hands had been affected. He only attempts this treatment in disfiguring, chronic, well-defined lesions, especially in psoriasis, after the failure of other methods. In eczema he finds the resistance to the desired effect increases progressively from the acute to the lichenoid form. He first softens the part with a permanent, soft potato cataplasm, not warm, frequently renewed, without antiseptics or oiled silk. The patient comes to the seance still "under the cataplasm." The scarifications are made in parallel lines, one to three millimeters apart, never crossed, in the superficial layer of the derma. The surface is allowed to bleed *ad libitum*, the bleeding promoted by tepid water, after which a folded piece of moist mull is applied and the patient returns to his cataplasm until the next seance. Six to sixteen are required. The scarifications are very slightly painful, even to children.—*Presse Méd.*, February 26.

Treatment of Puerperal Infections with Aromatic Essences.—A Spanish confrère has been following this method of treatment with "surprising and immediate success." He states that a single thorough application should be followed by a fall in the temperature in a few hours and he has never observed any secondary effects. He uses turpentine or essence of bergamot, and was led to attempt the treatment by his success in treating infected ulcers and wounds with turpentine. The essence is applied on a wad of cotton, inserted with curved forceps and the intrauterine surface painted with it, squeezing the essence well into the tissues, but never leaving it permanently. No speculum is required, although a preliminary vaginal irrigation

is advisable. This treatment has been applied to all cases at the Maternity and in his practice for over a year, with invariable success. One application a day is sufficient, except in case of gangrene or diphtheritic patches. He begs those who wish to observe the results of the treatment to apply it first in cases of infection of the vulva or entrance to the vagina, when they will see the aspect of the ulcerations alter before their eyes. Wherever applied the fall in the temperature is constant.—E. Corminas, *Rev. de Cienc. Med. de Barcelona*.

Myeloma of the Tendon Sheaths.—A. Venot calls attention to the danger of overlooking the pedicle which almost invariably extends from a myeloma in the sheath of a tendon into the adjacent articulation, although there is no evidence of it from without.—*Rev. de Chir.*, March 10.

The Favorable Effect of Calcium Carbide on Cancerous Growths has been confirmed by experience. In contact with moisture it splits into lime and acetylene gas, and applied to cancers of the cervix, the hemorrhage, fetid discharges and pains cease at once as if by magic. Livet and Guinard report many cases thus kept in a "happy *statu quo*" by an application every four or five days or at still longer intervals. (*Nouv. Remèdes*, February 24). There is a slight burning sensation which soon passes away.

Superiority of Japanese Paper Water Bags, etc., Over Rubber.—The expensiveness and lack of durability of rubber water and ice bags has led to much fruitless research to discover an efficient substitute for rubber. Jacobsohn announces that the Japanese rice paper articles of the kind are a distinct advance in the technique of the care and comfort of the sick. They are made of several layers of the soft, flexible rice paper used for so many purposes in Japan, with resin between, finished on the outside with a coat of the famous Japanese lacquer. He exhibited some air cushions thus made, at the meeting of the Berlin Society of Internal Medicine, March 7, demonstrating that the cushions were absolutely air-tight, flexible, "feather-light," remarkably enduring, bearing a permanent weight of 150 kilograms, folding into extremely small compass when not in use and costing less than a sixth of the corresponding rubber articles now in use. His report was made after long and careful personal tests.

Treatment of Chronic Coughs.—Dr. Adolph Goldhammer of New York, in the *Medical Record*, reports very favorable results in guaiacol treatment, in cases where no tuberculous element could be recognized. His first case was one in which the cough had existed for two years, and numerous other drugs had been used without avail. Under the use of guaiacol daily for one month the cough disappeared, and the patient has been entirely free from it ever since, a period of ten months. Since then he has used guaiacol in every case of cough of more than two weeks' duration, irrespective of origin. He has found it of decided value in cases of chronic bronchitis with or without asthma. In the chronic coughs of children guaiacol has proved especially beneficial. He has employed it even in several cases of whooping-cough with excellent results. The paroxysms were rendered less severe and less numerous, and the duration of the attack was cut short to two or three weeks. For children of a delicate temperament, who have a poor appetite and who occasionally have a slight cough, guaiacol is a valuable remedy. It stops a cough entirely in a short time, increases the appetite and causes the patient to gain in flesh. It is his opinion that many a case of incipient tuberculosis could be prevented if every old cough, no matter how slight, were treated by the administration of guaiacol. In acute coughs guaiacol does not act beneficially and should not be employed. In thirty cases of cough of varied origin and description he reports that twenty-six found the symptoms disappear entirely after the drug was used for periods of from two to six weeks. In the four remaining cases the cough was decidedly improved, although not entirely cured. Eighteen of these cases were in children under 10 years; nine were in adults, three of whom were over 65 years of age.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No., 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, APRIL 16, 1898.

CADAVERIC SPASM.

It has been occasionally observed in cases of sudden death after great and prolonged muscular tension and excitement that the body becomes instantaneously rigid in the position assumed at the moment of dissolution; thus a soldier is killed in action and remains fixed in the position of firing his piece, a lunatic after a prolonged period of excitement is found dead in the exact attitude of a convulsion or some other equally striking condition. Few have probably had the opportunity to observe this phenomenon, but its occurrence is incontestible though it has received little mention in physiologic or medico-legal treatises. Its explanation is not altogether easy on the usual theories of rigor mortis, notwithstanding the fact that the essential conditions are, in part at least, the same. There is the same muscular rigidity lasting a longer or shorter time and probably the coagulation of the myosin, which is assumed to be the cause of rigor mortis, also exists or very quickly supplements the muscular spasm that continues so strikingly in these cases. Rigor mortis notoriously appears quickly in hard-run animals killed in the chase and this is, except in degree, a strictly analogous condition. The condition appears to require a combination of three factors for its accomplishment—a sudden or rather an instantaneous death, a profound excitation or lesion of the nerve centers presiding over movement and an intense muscular contraction at the moment and article of death. Thus, these conditions are most often satisfied upon the battle field, where sudden death, excitement and muscular tension are all, we may say, normal happenings and the ghastly simi-

tude of vitality is hardly noted as out of the common course of events. Its rarity in civil life, if one may so call it, is the reason why it has so far escaped the sensational story teller, to whom it might afford, it would seem, a very appropriate climax for some tragic narrative. But even SAMUEL WARREN and CONAN DOYLE hardly appear to have utilized it.

A recent French thesis of Dr. MAZELLIER, a student of Professor LACASSAGNE, has treated the subject of cadaveric spasm from a medico-legal point of view, and offers some facts that are worthy of notice here. It gives the results of a series of experiments by LACASSAGNE and MARTIN on the possibility of this spasm being utilized in hiding homicide or in its detection. A murderer might, for example, put a weapon in the hand of his victim to suggest a suicide or to transfer the evidence of guilt of, it may be, still another crime. They find that it is possible to recognize the simulated grasp of a factitious suicide and the real cadaveric spasm of the hand with which, more often than is perhaps generally supposed, a real suicide holds the weapon. In the latter all the articulations of the hand combine to grasp the arm as in life and it is difficult to detach them, while in the former it is held stiffly between the rigid fingers and the palm. The fact that a localized cadaveric spasm of the hand sometimes occurs in suicides who have shot themselves in the head is itself a medico-legal fact of some considerable importance.

Another medico-legal point is that that cadaveric spasm itself is direct evidence of an instantaneous death. This need not be due to traumatism alone; it is in a certain proportion of cases due to an apoplectic stroke occurring suddenly while the subject is engaged in more or less strenuous muscular exercise of any kind. In these cases it is held that there is a sudden escape of blood into the ventricles causing by their sudden and excessive dilatation the same phenomena as were in the other instances due to the laceration of the brain substance by the gunshot wound. Whether this is exactly what occurs in all cases may be a question, the nervous shock from any sudden hemorrhage into the brain and more especially into those parts where such an accident would be instantly fatal, superimposed upon a condition of the muscular system induced by intense exertion, might easily have the same effect as a suddenly fatal gunshot wound of the brain. The fact is, however, of importance as it furnishes sometimes an indication of the cause of death where other and exterior signs are lacking. Such an instance is reported in M. MAZELLIER's thesis, where the medico-legal consultant was able before the autopsy to state the cause of death.

The important facts brought out in regard to this rare but occasionally happening phenomenon in this French physician's thesis, are that it may occur local-

ized in one member as in the cases of suicide alluded to, and that it is at times a possible and reliable indication of the lesion causing death when other indications are lacking. It is therefore something more than a mere medical curiosity: it has or may have at times a decided medico-legal importance.

THE VALUE OF THE SALIVA IN DIGESTING FOOD.

Even the merest tyro in physiology is familiar with the fact that the saliva not only prepares the food so that it can be readily swallowed and acted upon by the gastric and intestinal juices, but that it contains a ferment which possesses to a high degree the ability of commencing and even carrying to completion the transformation of starch into sugar, or in other words, the preparation of carbohydrate materials so that they can be readily absorbed and appropriated to the various uses of the economy. For many years when patients came to a physician complaining of symptoms of indigestion it was the custom to administer pepsin and hydrochloric acid under the erroneous idea that it was the proteids in the food which were not properly treated by the digestive juices and that relief could be obtained by aiding the stomach in the manner indicated. Only comparatively recently has the importance of pancreatin digestion been recognized as surpassing that carried out by the gastric juice and still more recently has the profession come to realize the fact that in many cases the predigestion of starchy foods or the administration of diastatic ferments capable of aiding in their digestion, is in a certain proportion of cases far more important than the administration of pepsin or pancreatin for their proteolytic action. Recent studies which have been made in the laboratories of Yale University emphasizes the value of the saliva as a digestive juice. They were carried out by Professor CHITTENDEN, who reported his results at the last meeting of the American Physiological Society in Ithaca. This investigator showed that great variations in the amyolytic power of the human saliva take place. Thus, he found that saliva collected before breakfast is stronger in amyolytic power than that secreted after breakfast. He also found that this greater power before a meal is not due to any increase in alkalinity but to the greater concentration of secretion coming from glands that have been resting. He also discovered that stimulation of the mucous membrane of the mouth by the vapor of ether or chloroform, or by any other substance which irritates that mucous membrane, causes a secretion richer in digestive powers and solid matters than that caused by mere mechanical stimulation. These observations are of interest not only because the importance of amyolytic ferments, both real and artificial, is attracting more and more attention from the profession, but also because two habits, supposed to be particularly prevalent among Americans, seriously influ-

ence the secretion of saliva, namely, the chewing of tobacco and the use of chewing-gum, the latter having become particularly common since the introduction of the bicycle. Professor CHITTENDEN's experiments indicate the fact that those persons with deficient digestion of the starchy articles of food should avoid chewing any such substances for a considerable period of time prior to a meal, as by this means the salivary glands will have an opportunity to rest and the liquid which they pour out when starch is taken will then be competent to digest its share of the meal. Where tobacco and chewing-gum are placed in the mouth and kept there until the time of the meal the salivary glands are not only unable to secrete enough amyolytic ferment to aid in the digestion of the starch, but are also unable to secrete enough fluid to thoroughly soften and disintegrate the food and as a result the indigestion of all articles of food ensues, since the pabulum when swallowed is not in a fit condition for gastric or duodenal digestion.

DOCTORS' BILLS.

There is probably at this moment no inconsiderable number of practitioners who are contemplating the gradually diminishing amount of their incomes, and not from the depths of easy chairs either. It warms the cockles of our hearts, no doubt, to read of the beautiful natures of our twin friends, "The Doctor of the Old School" and "Doc Sifers," and we are inclined to pass their imperfections or rather their impracticalities by, with but small censure. And that these dear old fellows are not entirely creatures of the imagination has been proven by the published accounts of the hundreds of letters from various parts of the English speaking world, each claiming a physician of the immediate neighborhood as the hero of MACLAREN's beautiful story. But it will be remembered that while lax in exacting payment, indeed often never asking any, this worthy pair were themselves the sole sufferers of their loose business methods. Did they have a collection of hungry mouths to fill, a contemplative reader, a business man, would be apt to look upon such neglect as criminal carelessness. The physician has always been looked upon as the poorest business man of any class in the civilized world. Even the clergyman has the good sense to look after his fee when performing the most sacred of all offices, and is not thought of any the worse. We need not mention the other of the great professional triumvirate, the lawyer. Yet should a doctor ask as to the forthcoming of his money before consenting to visit or take a case, the whole community would rise in arms at his heartlessness, and the rebuffed patient, the habitu  of a dozen doctors' offices, which he has honored with his presence but not with his money, makes it his main purpose in life for the time being to circulate that story, with each repetition a little

more exaggerated, to the ruin of that particular physician's practice. The doctor, while preparing his satchel for attendance, could ask all necessary questions as to when and how he is to be paid. He owes it to himself, he owes it to his family, he owes it to his brother practitioners, lastly, he owes it to the patient himself that he be not made a pauper. Because his patient is unable to pay, that need not interfere with his going—ye countless thousands of cases of daily self-sacrifice on the part of physicians bear witness—but if there is ability to pay, even moderately, he should know it and when the indebtedness is to be met.

Do not put off sending bills quarterly, half yearly; you are giving your clients' warm gratitude too much time in which to cool. You yourself receive regularly every month your bills from the grocer, the tailor, the landlord, and are expected to quickly liquidate; yet the writer has many times seen people visit upon their devoted physician's head their greatest displeasure that he should venture to send them a statement under three months, intimating that they were in the habit of paying their bills, and that they did not expect in the near future to change their places of residence. In vain the argument here suggested was pleaded as an excuse. They refused to be mollified. It is too late for some of the old ones to change, but the young doctors should see to it that they make a good start. Accustom the few patients that they have to expect statements on the first of every month, and to provide for just as they do for their other creditors, or you will not infrequently find that their quarterly bill has become so large that they give up all hope of ever being able to meet it. At such a time you will call to mind too late the old story of its being cheaper to move than pay rent. "In all your gettings," get business methods. This latter is one of the many valuable points general practitioners might copy from the specialists, and for which they have not been given sufficient credit. We stand aghast at their comparative success in collecting and feebly try to convince ourselves that the people will always pay specialists. Do not believe anything of the kind: there is always a feeling of disinclination to pay for anything which no visible collateral has been offered, the specialist as well as the general practitioner. Study the systematic business-like manner, the former goes about collecting his money and go thou and do likewise.

Another evil which should be promptly remedied: the habit of large business houses of sending injured employes to neighboring physicians and calmly repudiating the small bill rendered by the latter, is a matter of such common occurrence as to hardly need mentioning except to seek its remedy. The physician commonly makes the mistake of sending the bill to the injured party; he had then better give up all

hope, for that act relieves the firm of all responsibility in the matter and the patient either does not pay at all or only at a great discount. The cure is simple: it will take but a minute to call up by telephone the firm and find out definitely their responsibility in the case. Those who live in smaller towns, insist on your patient bringing you a note on the next visit, signed by someone connected with the house, stating that John Smith was injured in Mr. Jones' factory, and for Dr. Blank to kindly give him such attention as he may need. But in spite of the utmost precautions, there will remain a considerable percentage of what might be called "gross earnings" which will be as hard to get as blood out of the traditional turnip. Nevertheless be a business doctor, command your patients' respect in this regard no less than in your professional capacity, and you will be occasionally surprised in finding your efforts crowned with success, and a new book or coveted journal will be your witness to an honorable striving. Let us repeat, "with all thy gettings," get business methods.

THE WEEK IN CONGRESS.

In sanitary matters but little has been done. Dr. GALLINGER has succeeded in passing, through the Senate, bill 4190 "Authorizing the Secretary of the Interior to issue a permit to the American Invalid Society of Boston, Mass., to occupy and use 160 acres of land, being part of the abandoned Fort Stanton Military Reservation in New Mexico, for the purpose of a National sanitarium for the treatment of pulmonary diseases."

From documents accompanying the bill, it is understood that the "American Invalid Society of Boston, Mass." is a society that has in its membership such men as Rev. EDWARD EVERETT HALE, Dr. CHARLES R. NICHOLS, SOLOMON SCHINDLER (who is at the head of the Hebrew charitable societies of Boston), HEZEKIAH BUTTERWORTH, Mrs. JULIA WARD HOWE, Mrs. MARY A. LIVERMORE, and others.

This Society has already sent a great many poor people to the Rocky Mountain region at the expense of the Society, and they now purpose to equip this sanitarium. The bill as originally introduced proposed to grant the entire reservation of over 10,000 acres of land and the buildings thereon, but it was amended so as to grant 160 acres, which would seem to be ample for the purpose. There was no objection in the Senate to the passage of the bill.

RATES FOR THE DENVER MEETING.

On Saturday last the Special Committee of the Western Passenger Association reported to the general body in favor of allowing one fare and two dollars as the special rate to and from the meeting of the AMERICAN MEDICAL ASSOCIATION at Denver.

The question of time, which has been raised, was

not considered, although it is understood that the time limit will be thirty days, so as to allow of opportunity to attend the Omaha Exposition.

The route selected by the Committee of Trustees for the special train from Chicago to Denver, will be announced next week. In the meantime we respectfully request our readers to make their arrangements to go by the JOURNAL "special" from Chicago in preference to other routes.

CORRESPONDENCE.

Gynecology and Gynecologists in Paris.

PARIS, March 1898.

To the Editor:—It is an unfortunate attribute of human nature, that our thoughts and our actions, instead of flowing on in a steady and even current, are too often marked by great tidal waves that, rising to a certain height, settle back again to their original level. We seem in this respect to be governed by the same laws that govern the progress of great, wide-spread epidemics, like, for instance, the influenza which beginning at a certain point disseminates itself until it encircles the entire globe. Following the same law, we see level headed men, who have amassed a fortune by their economy and industry, seized by a speculative craze, and squander the savings of a lifetime in a single day. Religious epidemics attack communities and during their prevalence, men of small caliber are able to convert their thousands, while, when this wave of excitement has subsided, it takes a Sam Jones or a Booth to arouse the least spark of religious zeal.

Unfortunately for humanity, we, as physicians and surgeons, are not exempt from these periodic impulses, during the prevalence of which we lose our heads and resort to lines of practice that are contrary both to science and to sound judgment. One of the worst epidemic manias that ever struck the medical world, began about a decade and a half ago in Europe, and spread rapidly until it affected the profession of two continents. Abdominal surgery had just opened up a new field. The peritoneal cavity, which a few years before was a *terra incognita*, was invaded on all sides and by nearly everybody. The ovary was the point of attack. If not really diseased, it was accused of being the focus from which originated all the nervous phenomena to which that neurotic specimen of humanity, woman, was addicted. In their onslaught upon this organ, men vied with each other to see which could make the largest record, and then the foremost man in the contest, like the fastest horse on the trotting course, tried to beat his own record. Things went on in this reckless manner for half a score of years, and then men began to regain their reason, and only removed these important organs when they were seriously diseased.

About 1890, I believe, Dr. Péan advanced the idea that when the uterine appendages were diseased, and required to be removed, the uterus should be included in this operation.

This new departure appears to have been received with enthusiasm by a majority of operators here in Paris, who seem to be possessed with an irrepressible mania to remove the uterus, do a vaginal hysterectomy to relieve symptoms that viewed by the knowledge and light that one has attained away from here, seem most ridiculous and absurd. Up to this writing I have the notes of twenty-five operations of this kind, not including those done for fibroids and malignant growths, with the symptoms of the patients, and the pathologic appearances of the tissues removed.

As an example of the views held by prominent men on this subject, Paul Segond in a long article in the *Revue de Gynécologie* for 1897 lays down this rule: "When the annexes on both

sides are diseased and require removal, then remove the entire uterus, for of what use is it to leave a few grams of muscular tissue behind that has no function?" A more perfect drainage is another argument that he advances in favor of what he calls the complete operation.

Dr. E. Jayle in an article in the same journal says: "If the ovaries and tubes are removed, the uterus should also be. If the uterus and tubes are removed, leave the ovaries, if they are not involved in the morbid process."

Dr. V. Panchet in a late thesis, gives the results of 600 hysterectomies performed by Dr. Richelot at the St. Louis, about one-half of which were done by the abdomen, and the other half via the vagina. He was able to follow up about half of these cases and thus ascertain what the after-results of the operations were. 1. The sexual functions were not altered in a vast majority of these cases. 2. In one-fourth of the cases the pelvic and abdominal pains that the patients complained of before the operation were not relieved, owing probably to peritoneal adhesions that the operations did not remedy. Ninety-four per cent. of diseases of the annexes operated on by the removal of the womb, as well as the appendages, were cured while Dr. Richelot's operations done on the tubes and ovaries leaving the womb untouched, he had only 64 per cent. of recoveries.

Dr. Pozzi, to the American profession, is probably the best known gynecologist in France. As a teacher and a writer he has few equals, and though a skilful operator he can not be called the very best in Paris. He is a man 55 years of age, but looks ten or fifteen years younger, and has a bright, intelligent face and an eye that sparkles with intelligence and vim. He has probably the largest clientage among the wealthy of Paris, of any man in the city, has lately been elected to the senate, and all in all seems too busy to give that careful attention to his hospital work that other surgeons do. His teachings in the last edition of his "*Traité de Gynécologie*," in regard to the indications for the removal of the uterus with the annexes when the latter are diseased, seem to be wise and judicious. After remarking that following the practice of most American authorities on the subject, he usually prefers to open the abdomen in cases of diseases of the tubes and ovaries that require to be operated on he adds, "A vaginal hysterectomy ought to be preferred to a laparotomy in all cases where the annexes are strongly adherent to the uterus, and in cases where the supuration surrounds the wound itself." (*Peri metro-salpingite suppurée*). He further says that: "During the last two years I have practiced more frequently than formerly the removal of the uterus with the ovaries and tubes when the latter were diseased." Any one, however, who will follow Dr. Pozzi's work at the Broca, will at once be struck by the fact that his present practice in regard to the subject I am discussing is quite different from that taught in the last edition of his excellent work on gynecology. I give my notes on the first operation I saw him do this winter:

Patient, aged 35 years, has borne three children, the last one a year ago, since which date she began to complain of pelvic and abdominal pains, and her menses have been too profuse: no increase of temperature until within the last two weeks, since which she has had a temperature of 38.5 degrees C. every evening.

Diagnosis.—Metritis, salpingitis, ovaritis, and probably pus in both tubes. Vaginal hysterectomy done. Womb found slightly enlarged, and inner surface covered with dark granulations. Ovaries nearly healthy. Left tube enlarged to about double its natural size and closed at its uterine extremity. Right tube was about equally large and presented a slight protuberance at its center, and when opened was found to contain ten or fifteen drops of pus.

If this case had been curetted and the patient put to bed and free hot water injections used, would not this have had a tend-

ency to relieve the endometritis, to have opened up the left tube, and then if the lesion in the right tube had grown worse, could it not have been removed through an incision in the Douglas' pouch, and left the woman with her uterus, as well as one ovary and tube?

Prof. Jule Emile Péan, born sixty-eight years ago in one of the small provincial towns of France, has died. When a boy, in his early teens, his father had occasion to come to Paris to consult some professional celebrity on account of some disease from which he was suffering. The old gentleman was horrified at the size of the fee he was charged, and on his return home he patted his boy on the head and said: "My son, you must be a doctor, there are millions in it." The young man heartily embraced the idea advanced by his father, and if his professional confrères here in Paris do not falsify his character, he never lost sight of the motive that his father had in view when he launched him out into the world as a doctor.

From some cause or other Péan was thoroughly disliked by many of his professional colleagues here in Paris. A prominent gynecologist speaking to me of him on the day of his funeral, remarked: "His audacity and industry were unbounded." Whatever prejudice may have existed against him while living, his contributions to gynecologic surgery and his *forcipressure* for the control of hemorrhage, are honors of which no one can rob him and which will render him immortal as a surgeon. Still, when all this is said in his favor, I think it can be affirmed with perfect truthfulness that his death left no blank in the profession that others can not fill better than he did.

Though the originator of many new ideas, he never would accept any modification of any procedure that he himself had devised. I saw him do, at the Hospital International, I believe the last operation he ever performed. It was the removal of a large fibroid through the vagina by *morcellement*. The operation was a long and tedious one, and perhaps justifiable when no better technique was known for the performance of an abdominal hysterectomy than that devised by Freund, but certainly not a justifiable one when viewed in the light of our newer modes of doing this operation. I have seen considerable of Dr. Péan from first to last. He was a prominent figure at all our International Congresses and with his giant frame and manly bearing attracted universal attention. While he was a professor of surgery in the School of Medicine of Paris, and taught at the St. Louis, I saw considerable of his work, and though he was a brilliant lecturer and a daring operator, viewed from my Anglo-Saxon standpoint, I never considered him a safe model to follow. To illustrate, some years ago a patient was put upon the table, suffering from an empyema of the left side of the chest. He was chloroformed and a portion of a rib resected, and then a free incision was made into the pleural cavity from which gushed two or three liters of pus. In three minutes more the patient was dead. Had he used less anesthetic, or substituted ether for his chloroform, and removed this fluid more gradually, perhaps this man's life might have been saved.

Professor Richelot is a man about 50 years of age, quiet, modest and unassuming in his manner and thoroughly devoted to his work. He operates three times a week at the St. Louis and if one follows him, he will see more gynecologic work than can be seen at any other operating clinic I ever followed. Whatever other operations he does, you can generally depend upon seeing a hysterectomy, either vaginal or abdominal, on any one of his three operating days during the week. Dr. Richelot has done nearly four hundred abdominal hysterectomies, a record that I suppose few, if any, have exceeded. I asked him what had been his mortality in this operation. His reply was: "Dr. C., do you want me to lie to you, as men generally do when giving their statistics? If you do, I will say 2 or 3 per cent., for that is the fashion, but if you want me to

tell you the truth, I will tell you that my mortality in my first hundred cases was 7 per cent., or over, but now in the uncomplicated cases I am only losing about 5 per cent."

To illustrate how even so good a diagnostician as Dr. Richelot is, may be deceived and make an erroneous diagnosis, I cite the following case:

Patient aged 42 years, mother of seven children, looks fairly well nourished, complains of pain in back and loins and has been flooding for three months. Diagnosis: Uterine fibroid with retroversion. Vaginal hysterectomy done. When the cervix was opened it was found to contain a large blood clot. When the uterus was opened, out burst a fetus of about three and one-half months. This accident did not at all unnerve the Dr., who justified himself by giving examples in which eminent men had committed the same blunder.

The following case will illustrate the difference in the practice of the Paris school of operators, as compared to that pursued by Dr. Tuttle of New York, and many other Americans: Patient aged 32 years, aborted six months ago, since which she has had pains in her back and loins, and a slight rise of temperature every afternoon. Vaginal examination showed uterus to be fixed and immovable, with a hard mass filling Douglas' pouch and extending toward the left side. A vaginal hysterectomy was done, but before the operation was completed, a large pus sac situated behind the uterus was ruptured. The ovaries and tubes were matted together in this inflammatory exudation, and neither these nor the pus sac could be removed. So the Doctor finished the operation by packing the abscess cavity with gauze, explaining that he did not deem it essential to remove the abscess walls. Dr. Tuttle would have opened up this abscess by a free incision behind the uterus, drained it with gauze, and hoped to cure his patient, leaving her uterus, tubes and ovaries intact. If one reads his text-books or witnesses the operations of different operators, he will be struck by the lack of uniformity of the teachings of the former, and the practice of the latter in their technique for doing a vaginal hysterectomy.

It is understood that in France, as far as my observation goes at least, the forceps are always used as a means of controlling hemorrhage. Richelot's mode of operating strikes me as a good one and is as follows:

1. Draw the uterus well down with your forceps and make a circular incision around the entire neck, usually about one inch above the os, and let this incision be deep enough to include all the tissues down to the muscular substance of this organ.
2. Dissect loose all the connections between the cervix and vagina upward, until you can feel the pulsation of the uterine arteries on each side.
3. Open up widely the vesicovaginal connections in front, and the rectovaginal connections behind, until you have entered the peritoneal cavity at each point.
4. Clamp the uterine arteries on each side and continue your dissections upward, until you have reached the union of the body of the uterus with the cervix. Introduce a retractor into the anterior space between the bladder and the uterus and raise the former well upward.
5. Split open the cervix and amputate it at its junction with the body, at the same time keeping firm hold with your forceps of the lower part of the latter. With your retractor in place and the tissues raised well upward, you have a plain view of the whole anterior aspect of the body of the uterus.
6. Begin now and split this open with your scissors, and as you do so draw the organ down, so that by the time you have reached the fundus with your incision, the uterus is delivered outside through your vesicovaginal opening. Pull the body forward and continue your incision until the womb is split into two halves.
7. Introduce your fingers between these two halves of the

uterus, and pull one of them well forward. You have now the broad ligament, the tubes and ovaries on one side in plain view.

8. Clamp now, with a pair of long forceps, from *above downward*, the broad ligament, and cut away the one-half of the uterus. Repeat this on the other side.

Richelot lays great stress on this mode of applying the forceps, and by this manner of procedure avoids the accident of wounding the ureters, which he has only done once in 300 operations. The field of operation is now carefully inspected, and all bleeding points are caught by forceps, so that when finished there are generally from eight to ten forceps applied. The vagina is then tamponed as high up as the peritoneal opening with tampons of sterilized wool on which iodoform is well sprinkled. The forceps are removed after forty-eight hours, but these tampons are left for six days longer, or until vaginal injections can be safely used.

While the above technic for doing a vaginal hysterectomy is that adopted by a majority of those I have seen do this operation here in Paris, the several men I have seen perform an abdominal hysterectomy seem each to have a procedure peculiar to himself. However, as I like that adopted by Richelot better than anything I have seen elsewhere, I will briefly give his mode of operating: The patient is put in the Trendelenburg position. The incision in the abdominal walls is made large enough to easily deliver the uterus on the outside.

1. Catch the uterus and have an assistant raise it well up, at the same time putting in a wide retractor at the lower angle of your incision that will spread the parts well asunder.

2. Make an incision laterally through the serous and cellular tissue of the uterus at its anterior aspect, some distance above the bladder.

3. Separate these tissues with the fingers, down as far as the cervix.

4. Begin now on the side and put two clamps on the broad ligaments side by side, and make your incision between these clamps. The structures on the sides are then clamped and cut away until the uterine artery is reached, and this is caught with a small pair of forceps, drawn upward and cut away from its attachment to the cervix.

5. The uterus is now tilted backward and by dissecting from above downward, keeping close to the neck of the uterus, the anterior aspect of the cervix is separated from its vaginovesical attachment and thus the whole anterior aspect of the uterus is freed.

6. Tip the uterus forward and divide the tissues at its posterior aspect laterally, as you did in front, and dissect these down behind until you have entered the vagina as you had down in front, and this done you have entirely separated the uterus from all its attachments.

7. Sew up the vaginal opening in the floor of the pelvis.

8. Lastly, unite with catgut sutures your flaps of serous tissue that you have peeled from the sides of the uterus.

When your operation is done the floor of the pelvis is one continuous even surface, with nothing to show that it had ever been disturbed except the two united surfaces of your serous membrane.

W. S. CALDWELL, M.D.

(To be continued.)

Acute Pyelonephritis after Ovariectomy.

Oconomowoc, Wis., April 10, 1898.

To the Editor:—Mrs. F., aged 28 years, mother of five children came Jan. 3, 1898, for the removal of an ovarian cyst. The patient was in fair condition weighing 130 pounds. She complained of the usual symptoms caused by the presence of a cyst only to a moderate degree. The usual very strict preparations were carried out by our nurses during the three days previous to the operation. The A.M. and P.M. temperature was

normal and the interne found nothing abnormal about the urine, making several tests. A trial aspiration proved the contents of the cyst to be opaque and gelatinous, the cyst multilocular; there were no adhesions and a well formed pedicle. The operation consumed, therefore, but a short time, and the patient was in bed in twenty-five minutes.

After the operation the patient complained of a great deal of pain in her back and limbs, in fact all over; more so than usual in such cases. The temperature fluctuated between 99 and 100 degrees. There was no tympanites and no pain on pressure over the abdomen, but she was more or less uneasy and the urine had to be drawn as the patient was unable to void it during the first week. The urine was drawn under the most strict precautions, the passing of the catheter was however continually uncommonly painful to her, and the nurse reported that the patient had complained quite a little of pain in the urethra, when the urine was drawn before the operation. After the seventh day she began to void urine, but in connection with much tenesmus and quite frequent, these symptoms increased the next two days, and it became evident that the patient suffered from acute infectious cystitis. During the last ten years we never had a cystitis developed after an operation and I was at a loss how to account for it, as I have absolute faith in our matron and nurses.

The patient suffered quite a little from the cystitis, which was nearly well at the end of another week under the usual treatment and strict diet: the temperature had become nearly normal. However, on the seventeenth day after the operation very severe pains set in in the left side, together with a rise in temperature, some vomiting and great prostration. The urine again contained pus and blood cells, showing that the infection was passing up the left ureter. In spite of the continuation of the bland milk diet, etc., the application of ichthyol ointment to the left side and the administering of boric acid, urotropin, etc., the pain gradually traveled upward, several chills followed and the left kidney became also affected. The patient was now in a very deplorable condition; and temperature 104.5 degrees; pulse 106; respirations 22 to 28; profuse perspiration, anorexia, nausea and feeling of hopelessness. The continuous pain caused the patient to collapse decidedly, as urotropin, boric acid, alkaline mineral waters with hot milk, etc., had apparently no effect on the progress of the disease. Pyoktanin was given in capsules by the mouth, but not tolerated by the stomach, then benzoate of sodium was given, all without effect. We despaired of saving our patient. As the bladder was less sensitive we began to irrigate it with lactate of silver Credé 1-1000 twice a day, to destroy what germs we could in that organ: an ichthyol mercurial ointment was applied thickly over the region of the affected kidney, and over it hot fermentations with a diet of hot milk and selzer, somatose, almond emulsion and, as an internal germicide, salol gr. xv, four times a day.

In urotropin I was disappointed, as it always had very beneficial effect in cases of subacute and chronic cystitis before; in this case it failed. Perhaps it passed the kidneys too quick, and the continuous acid reaction of the urine in this case may have had an influence upon its not acting. For the next two days the patient remained in the same condition, then the temperature went down to 101 degrees, and the pain lessened. The patient had some refreshing sleep and the urine improved from day to day, pus and blood cells diminished, and January 26 the patient again had a normal temperature. The convalescence was not again interrupted and on February 10 the patient was able to go home.

How did this infection of the urinary tract originate? A number of microscopic examinations of the urine revealed mostly streptococci. An infection from the vagina was excluded, as there was no discharge from either uterus or vagina; besides the vagina had been sterilized, and in addition lysol douches had been used daily. On questioning the patient, she said,

that for several years she had had frequent and painful micturition. As soon as the patient was well enough, a careful examination of the urethra was made, when the source of the infection was at once revealed. The posterior third of the urethra was found ulcerated up to the neck of the bladder. This experience taught us, that it is wise to investigate the urethra of patients who complain of painful micturition, before undertaking a laparotomy or an operation, after which a catheter is expected to be used.

The urethral ulceration was treated twice a day with a 1 per cent. solution of lactate of silver, and healed rapidly. On leaving, the patient received a 5 per cent. solution of lactate of silver and an eye dropper and was instructed how to inject her urethra twice a day at home.

The stitches of the abdominal incision were removed eight days after the operation, union being by first intention.

J. H. VOJE, M.D.

Post-Graduate Extension Lectures.

BELLOWS FALLS, VT., April 9, 1898.

To the Editor:—In reading your editorial of March 26 (page 739), on "Post-Graduate Lectures at Home," I was much pleased with the suggestions you offered. It is a plan that has been carried out, in part, by our Society for a good many years. We have had such men as Prof. Conner of Cincinnati, Prof. Hanks of New York, and others. Of late years we have had in operation a plan that has been more fruitful of results in every particular. The Society of which I am Secretary, viz., the Connecticut River Valley Medical Association, with White River Medical Association and the White Mountains Medical Association, have, through the kindness and generosity of Dartmouth Medical College, held a joint meeting at Hanover, and the Professors have given us lectures on their special branches. We have also had some specialists from outside. The expense of printing, etc., has been arranged between the three mentioned societies, and it has been practically nothing. We have a plan which, it seems to me, is a step in advance of the good one suggested by you in the JOURNAL, and could be made of general use in all parts of the country by other local societies. It is a plan that I have never seen or heard of before, although it may have been in operation for years. Dr. Godfrey would not have to ask for volunteers for their next meeting as they could then join with others and meet at some convenient place and do as we are doing now.

Faternally, J. SUTCLIFFE HILL, M.D.

ASSOCIATION NEWS.

Medical Societies Entitled to Representation in the American Medical Association, Jan. 1, 1898.—

"The delegates shall receive their appointment from permanently organized State medical societies, and such county and district medical societies as are recognized by representation in their respective State societies, and from the medical departments of the Army and Navy and the Marine Hospital Service of the United States.

"Each State, county and district medical society entitled to representation shall have the privilege of sending to the Association one delegate for every ten of its regular resident members, and one for every additional fraction of more than half that number: *Provided*, however, that the number of delegates for any particular State, Territory, county, city or town shall not exceed the ratio of one in ten of the resident physicians who may have signed the Code of Ethics of the Association.

"*Members by Application.*—Members by application shall consist of such members of the State, county and district medical societies entitled to representation in this Association as shall make application in writing to the Treasurer, and accompanying said application with a certificate of good standing, signed by the president and secretary of the society of which they are members, and the amount of the annual subscription fee, \$5. They shall have their names upon the roll, and have

all the rights and privileges accorded to *permanent members*, and shall retain their membership upon the same terms."

In accordance with the above extracts from the Constitution, this list is prepared as certified by the secretaries of the State and Territorial medical societies.

Any societies that are omitted should send to the office of the Permanent Secretary notice to that effect accompanied by a certificate from the secretary of the State society that said society is so recognized in accordance with the above quoted law.

WM. B. ATKINSON, Permanent Secretary,
1400 Pine Street, Philadelphia.

Section on Ophthalmology.—The preliminary program of the
Section on Ophthalmology comprises the following papers:

An Easily Overlooked Form of Keratitis, by Henry Gradle,
Chicago.

Remarks on DeZeng's Refractometer, by Frank Allport,
Chicago.

The Clinical Aspects of Toxic Amblyopia, by Casey A. Wood, Chicago.

Some Experience with Extirpation of the Lachrymal Sac, by J. E. Colburn, Chicago.

An Additional Case of Double Microphthalmus, by Cassius Wescott, Chicago.

The Treatment of Corneal Ulcers with Pure Oxygen, by T. H. Woodruff, Chicago.

Some Uses of Electricity in Ophthalmic Practice, by H. M. Starkey, Chicago.

Treatment of Disorders of the Lachrymal Apparatus, by Leartus Connor, Detroit.

Glaucoma and Detachment of Retina, by W. Cheatham, Louisville.

Phlyctenular Keratitis, by D. S. Reynolds, Louisville.

The Treatment of Blepharitis with Formalin, by Herbert Moulton, Ft. Smith.

The Dynamics of the Extrinsic Ocular Muscles as the Result Obtained by the Examination of 100 Medical Students, by F. B. Tiffany, Kansas City.

Regular Astigmatism is not always Congenital, Neither is it Unchangeable, by Wm. C. Bane, Denver.

The Use of Large Probes in Strictures of the Lachrymal Duct, by G. M. Black, Denver.

Galvanism in Choroiditis, by R. F. LeMond, Denver.

The Treatment of Suppurative Dacryocystitis, by Arthur Prince, Springfield.

A New Perimeter, by C. H. Williams, Boston.

Eye Muscle Tests with Colored Glasses, by Frank B. Eaton, San José, Cal.

Report of a Few Cases of Acute Glaucoma, by H. Bert Ellis, Los Angeles.

Report of a Case of Quinin Amaurosis, by J. M. Ball, St. Louis.

Extirpation of the Lachrymal Sac and Gland, by C. R. Holmes, Cincinnati.

The Field of Fixation or the Home of the Guiding Sensation, by G. C. Savage, Nashville.

Additional Notes on the Employment of Absorbable Sutures in the Operation of Looping the Tendons of Ocular Muscles, by J. O. McReynolds, Dallas.

The Pathology of Toxic Amblyopia, by G. E. de Schweinitz, Philadelphia.

The Frequency of Senile Opacity in the Crystalline Lens and the Proper Definition of Cataract, by Edward Jackson, Philadelphia.

The Treatment of Epiphora and Affections of the Lachrymal Apparatus, by Samuel Risley, Philadelphia.

The Uses of Electricity in Ophthalmology, by S. Lewis Ziegler, Philadelphia.

Use of Aluminium for an Artificial Vitreous, by D. C. Bryant, Omaha.

Some Severe Cases of Tobacco and Quinin Amblyopia, by E. C. Ellett, Memphis.

Unsatisfied Sexual Desire a Cause of Heterophoria in Both Sexes, by L. R. Culbertson, Zanesville.

Report of a Case of Hemorrhagic Retinitis (idiopathic?), by Vard H. Hulen, Galveston.

A Demonstration of the Sideroscope of Asmus, by A. Barkan, San Francisco.

Amblyopia from Auto-intoxication, by Henry B. Young, Burlington.

SOCIETY NEWS.

New York State Medical Association.—The fourteenth annual meeting of the New York State Medical Association, Third District Branch, will be held at Syracuse, N. Y., June 2, 1898. F. W. Higgins, Secretary, Cortland, N. Y.

Southwest Missouri Medical Association.—The twenty-second annual meeting of the Southwest Missouri Medical Association will be held at Cape Girardeau, Mo., May 3, 4 and 5. M. Rosenthal, Corresponding Secretary, Kennett, Mo.

Tri-State Medical Society.—The following officers were chosen at the recent meeting in Dubuque, Iowa: President, C. E. Ruth, Keokuk; Vice-president, Dr. Murphy, St. Louis; Treasurer, Dr. Fairchild, Clinton, Iowa; Secretary, Dr. Fowler, Dubuque.

Kentucky State Medical Society.—Dr. H. K. Adamson, the Chairman of the Committee of Arrangements, reports progress in

his arrangements and believes that the indications give promise of a full and profitable meeting in Maysville on May 11, 12 and 13. That city has always sent a large and influential delegation to the meetings in other towns, and there is no doubt that the compliment will be returned with interest. Moreover, Maysville presents peculiar features in that it is the most northern and eastern point available for State society meetings. A large number of physicians from Cincinnati and other Ohio cities may be expected, while the blue grass contingent may be expected to turn out in full force. —*Am. Practitioner and News.*

American Microscopical Society.—The next meeting of this Society will be held in Syracuse, N. Y., Aug. 30, 31, and Sept. 1, 1898. The Society is invited to meet in Syracuse by the Academy of that place. The daily sessions of the Society will be held in the new building of the College of Medicine, Syracuse University. The building is centrally situated, has commodious lecture-rooms well suited for the work of the Society. Its laboratories are ideal rooms for trade displays of apparatus or for a working session; and in the evening an exhibition soiree, which will probably be made an important part of the exercises. The time of this meeting has been so fixed as to make it convenient for members of the American Society for Advancement of Science, on leaving Boston, to attend the Syracuse meeting on their way home.

Society of Internal Medicine.—A meeting of Chicago physicians was held in the Chicago Medical Society Rooms, Thursday evening, April 7, 1898, to organize a Society of Internal Medicine, devoted especially to the interests of the general practitioner. Dr. J. H. Hollister was elected Chairman of the meeting, and Dr. John A. Robison, Secretary. The question came up as to whether a separate society should be formed, or whether it should be a department of the Chicago Medical Society. Speeches were made *pro* and *con* by Drs. Ware, Davis, Jr., Lyman, Thomas, Billings, Hollister, Robison, Favill, etc., the consensus of opinion being that it was desirable to have the Chicago Medical Society so broadened as to include all branches of medicine—a very sensible conclusion. A committee of five was appointed to confer with the Chicago Medical Society relative to broadening its scope.

American Medico-Psychological Association.—The fifty-fourth annual meeting of the American Medico-Psychological Association is to be held at the Southern Hotel, St. Louis, May 10 to 13 inclusive. The program for the meeting includes a large number of papers of interest, and the annual address will be delivered by Dr. J. T. Eskridge of Denver, the subject being "The Mutual Relations of the Alienist and Neurologist in the study of Psychiatry and Neurology," certainly a living question at the present day, and one that will be interestingly handled by the speaker. The meetings of this organization have of late years been more and more attended by neurologic specialists, and the coming one in such a medical center as St. Louis, will probably have a larger attendance of those not directly connected with the specialty of psychiatry than has been always the case.

PUBLIC HEALTH.

International Prophylactic Measures are not restricted to the bubonic plague and cholera alone in Europe. The principality of Montenegro has established a military cordon and quarantine along the border to protect the country from an epidemic of smallpox now raging at Scutari, a town of 36,000 inhabitants over the line in Albania. *Sem. Méd.*, March 19.

Sanitaria for Tuberculous Patients.—In Germany Stettin already has an institution with accommodations for eighty inmates, erected at an expense of 350,000 marks; one in Thuringia is to be opened in July, and others at Wiesbaden and Munich

are progressing favorably. The Congress of Naturalists and Physicians, which is to convene at Dusseldorf in September, has appointed a standing committee for this matter. We notice in this connection the negative results obtained from an exhaustive study of the vital statistics of the region surrounding Davos in the Engadine, from which it appears that the population living in and around tuberculosis resorts are not exposed to greater danger of contagion than others elsewhere.

Smallpox in Alabama.—Smallpox was declared to be present in epidemic form in Birmingham, Ala., as long ago as in July, 1897, by the Board of Health of Jefferson County. At the close of 1897 there had been reported 406 cases, with 15 deaths. The epidemic has been of mild type, and chiefly confined to the negro population. As a writer in the *Medical News* explains, there is in every county in Alabama a Board of Health which has well-defined powers and a legal status. Every county health officer in the State is required by law to furnish vaccine free of cost at all times. There is, however, no compulsory vaccination law in the State code. There is a large proportion of the population who will not submit to vaccination when it is voluntary. Under the charter of the City of Birmingham the Council has power to pass a compulsory vaccination law, and upon request of the Board of Health proceeded to pass it as soon as smallpox was declared epidemic. A corps of vaccinators, house disinfectors and inspectors was appointed without delay, and during the next three months the vaccination corps went over the city four times. Daily reports were published and sent to the journals. After some three months the epidemic was so well under control that most of the inspectors and vaccinators were discharged, and later, when no new cases were reported during four weeks, the epidemic was declared to be at an end. Cases, soon, however, began to appear, being imported into the city and country, and the health machinery, consisting of pest-houses, detention-camp, inspectors, ambulances, etc., was for a time continued in operation. Good and efficient work has been done by Dr. McGruder, one of the ablest officers of the Marine Hospital Service, but perfect results have not been attained, for smallpox has not been eradicated. More than \$20,000 has been expended by the county and city authorities, and a vast amount by the Marine-Hospital Service. The reasons for this failure are plain: absence of a State compulsory vaccination law, a prejudice against vaccination and, lastly, the mildness of the disease during the present epidemic. Had the disease been of the ordinary type, as regards severity, it is safe to assume that systematic concealment of cases could not have been practiced by the colored population. The truth has been that many of them seemed to dread the sore arm incident to vaccination more than they did the mild smallpox, which, in not a few instances, did not even confine them to bed. This mildness was especially observed in children, contrary to the usual rule. Regular detective work was required of the Government inspectors in their efforts to find the cases, such were the expedients employed to conceal them. When smallpox will be eradicated from Alabama and adjoining States is problematic; certainly not until compulsory vaccination laws are passed, accompanied by large appropriations for their enforcement. The disease has been in lower Alabama for nearly a year and a half, having been introduced from an adjoining State. From a medical standpoint the interesting feature has been the extreme mildness of so many of the cases.

BOOK NOTICES.

Surgical Pathology and Principles. By J. JACKSON CLARKE, M.B., F.R.C.S., with 191 Illustrations. Longmans, Green & Co., London, New York and Bombay. 1897. Pp. 440.

This work is divided into two parts, the first of which is

devoted to general surgical pathology, and contains chapters on repair, inflammation, infective inflammation, new growths, dermoids and malformations. Part II is given to diseases of special tissues and organs, and contains chapters on diseases of bone, jaws and teeth, joints and bursæ, muscles and tendons, nerves, diseases of arteries, diseases of veins, lymphatic vessels and glands, mouth, tongue and alimentary tract, abdominal hernia, intestinal obstruction and peritonitis, diseases of salivary glands, liver and pancreas, respiratory tract, thyroid gland, acromegaly; brain, ear, eye; spinal column and cord; deformities of the extremities; urinary tract, testes, etc.; female generative organs, the breast, and the skin.

This work is very concise and contains the essentials on the subject of surgical pathology. There are few omissions, and if there are any errors we have not encountered them. The work is well printed.

Atlas and Essentials of Pathological Anatomy. By O. BOLLINGER, M.D., Volume I. Circulatory, Respiratory and Digestive Apparatus, including the Liver, Bile Tracts, and Pancreas; with 69 colored figures upon 60 plates, and 18 illustrations in the text. New York: Wm. Wood & Co., 1898. Pp. 246.

This little volume is one of the Wood Series of medical hand atlases. For beauty of illustration, interest of subject-matter and practical value, it can hardly be surpassed. The second volume of this atlas is in press and will soon be issued. This volume includes pathologic anatomy, circulatory apparatus, lymphatics and blood vessels, diseases of the respiratory organs, diseases of the digestive apparatus, the liver, bile ducts, and pancreas. The illustrations are beautiful and the coloring extremely natural. Appended to each plate we find an explanatory text, together with a brief clinical history of the case from which the specimen was taken. We commend the book.

Studies From the Yale Psychologic Laboratory. Edited by EDWARD W. SCRIPTURE, Ph. D. Vol. iv, 1896. Paper. Pp. 141. Illustrated. Yale University, New Haven, Conn.

The following papers are included in this volume: "Reaction-time in Abnormal Conditions of the Nervous System," by A. G. Nodder; "Researches on Reaction-time," "Researches on Voluntary Effort," "New Apparatus and Methods," and "Elementary Course in Psychologic Measurements," by E. W. Scripture; "Influence of the Rate of Change Upon the Perception of Differences in Pressure and Weight," and "Weber's Law in Illusions," by C. E. Seashore.

The International Medical Annual and Practitioner's Index: A Work of Reference for Medical Practitioners: Sixteenth Year, New York: E. B. Treat & Co. Pages 740. Price \$3.00.

The Annual for this year surpasses in excellence of material the general make-up of any previous issue of this well known reference book. It is an excellent lexicon of our literature, and the low price at which it is sold makes it especially desirable. Among the several year books the International justly takes front rank.

Transactions of the Nineteenth Annual Meeting of the American Laryngological Association. Cloth. Pp. 200. Illustrated. New York: D. Appleton & Co., 1898.

This volume covers the work of the session held in Washington, D. C., May 4, 5 and 6, 1897, and contains the following papers: "Guaiacol as a Local Anesthetic in Minor Operations on the Nose and Throat;" "Sub-mucous Hemorrhage of the Vocal Cords;" "Hysterical Dysphagia;" "Remarks on Treatment of Chronic Affections of the Faucial Tonsils, with Demonstration of Instruments;" "On the Treatment of Chronic Frontal Sinusitis by Means of an Opening Through the Anterior Wall of the Sinus and Drainage Through the Nose;" "Papillary Edematous Nasal Polypi and their Relation to Adenomata;" "A Case of Adenocarcinoma of the Nose;" "Atrophic Rhinitis: Its Nature and Symptoms;" Remarks on Atrophic Endorhinitis;" "Treatment of Atrophic Rhinitis;" "Tertiary Ulceration Simulating Sarcoma of the Tonsil;" "New Method for the Relief of Certain Enlargements of the

Turbinated Bodies;" "Case of Angeioma of the Tonsil, with Recurrence Three Years after Removal;" "Case of Sub-glottic Fibroma; Removal by Tracheotomy and Curetting;" "Contribution to the Study of the Treatment of Laryngeal Phthisis;" "Primary Lupus of the Larynx;" "Sarcoma of the Nasal Passages;" "Angeioma of the Nose;" "Nasal Bacteria in Health;" "Supplementary Note on a Case of Martin's Bridges for Depressed Nose."

Transactions of the Berks County Medical Society, for the year ending Dec. 31, 1897. Paper. Pp. 121. Reading, Pa., 1898.

The volume contains, in addition to society data usually found in transactions, the following papers: "Address of President;" "An Essay on Sanitarians and Sanitation;" "Pulsating Empyema;" "Tubal Pregnancy and Appendicitis;" "A Case of Simulated Pregnancy Going on to Labor;" "Uterine Fungosities and the use of the Curette;" "Pleuritic Effusions;" "Intestinal Hemorrhage in Typhoid Fever;" "Fever in its Treatment;" "Cystic Liver;" "Foreign Bodies in the Eyeball;" "Refraction Errors as a Cause of Reflex Disturbances;" "Treatment of Croupous Pneumonia."

NECROLOGY.

WM. H. JOHNSTON, M.D., New York University Medical College 1867, of Birmingham, Ala., died there April 3. He served on the Confederate side during the war, before which he was for one year a medical inspector of the department of public charities, New York city.

AMBROSE M. MILLER, M.D., Lincoln, Ill., died April 2. Doctor Miller was a former member of the Legislature and superintendent of the State asylum for the feeble-minded. He was graduated from the Washington University Medical School in 1853, and a member of the Illinois Army and Navy Medical Association.

WILLIAM BLAND BIRD, M.D., Baltimore, Maryland University 1892, April 4, aged 25 years.—Charles A. Brun, M.D., Columbus, Ohio, March 29, aged 28 years.—Henry G. Buckingham, M.D., Clayton, N. J., April 4, aged 61 years.—A. F. Chase, M.D., Philadelphia, April 2, aged 60 years.—John J. Cullinane, M.D., Buffalo, N. Y., March 31, aged 31 years.—J. M. Dunlap, M.D., Manheim, Pa., Jefferson 1845, April 4, aged 76 years.—Lloyd H. Smith, M.D., Easton, Md., April 3, aged 45 years.—Elbridge G. Stevens, M.D., Old Orchard, Me., March 26, aged 87 years.—John Albright, M.D., at his residence in Madison, N. J., April 2, aged 82 years.

MISCELLANY.

State Board Examinations.—The JOURNAL of March 26 contained a list of States requiring all graduates to stand examination before the State Board. We are informed that Massachusetts also requires examinations of all except graduates from its own schools.

Prizes for the Investigation of African Diseases.—A gift of \$5000 to be used in promoting the study of the diseases of the Congo, has been received by the Society of Colonial Studies of Brussels, and the Society offers two prizes of \$500 for some notable addition to the knowledge of the evolution of the hematozoön of Laveran and for the discovery of the origin of hemoglobinuric fever.

Irregular Hours and Small Pay.—The stranger remarked: "I think I can tell what your business is." "What?" "Night watch." "No, friend, you are mistaken: they can go to sleep on their beat and they draw their wages regularly." "Well, then you're a fireman, ain't you?" "Worse than that; no such regular pay or sleep for me." "Well, what are you then?" "Why, I'm a doctor: one of those unfortunate fellows who are called up so often that they don't know night from day, excepting when they get out of town, and never draw their pay while they are away, either."

A French Commission on Tuberculosis.—On the motion of M. Brouardel, the Paris Academy of Sciences has appointed a commission to study the question of propagation of tuberculosis. The commission is to consist of the six members of the section of medicine and surgery, the two permanent secretaries and MM. Brouardel, de Freycinet, de Jonquières, Chauveau, Duclaux, Arm, Gautier.

Leukemia in a New-born Infant.—L. Pollmann reports a case of pronounced leukemia in an infant born of healthy parents, without syphilitic antecedents. On account of the verrucous endocarditis found at the necropsy the nineteenth day after birth, Pollmann is inclined to ascribe the origin of the leukemia to some infective process which affected the mother during her pregnancy, but which remained latent as far as she was concerned.—*Muench. med. Woeh.*, January 11.

The Brooklyn Ambulance System.—Dr. Robert A. Black, who, under the title of an Assistant Sanitary Superintendent, is the highest sanitary official in the borough of Brooklyn, city of New York, has been compelled by lack of funds to discontinue two ambulances that have for twenty-five years been run by the Brooklyn Health Department as "City Ambulances." Their stations were at the Long Island College Hospital and at the Eastern District Hospital for service in the two main districts of the city, or borough, respectively. If these two institutions are to have ambulance stations of their own in the future it is probable that they will be compelled to find their own funds for that end, as is done by various other hospitals that have their private ambulances.

Rush Medical College out of Debt.—The affiliation of Rush Medical College with the University of Chicago is now practically assured, the debt of \$71,000 on the college having been paid off by members of the faculty and friends of the institution. Principal among those who rendered this assistance are: Drs. Ephraim Ingals, Nicholas Senn and E. Fletcher Ingals. When the affiliation was announced by President Harper of the University of Chicago (*vide JOURNAL*, p. 101), it was conditional on the wiping out of the debt of \$71,000, the change in the methods of choosing trustees, and the advance requirements for students.

Donation to the East Brooklyn Dispensary.—Mr. Henry Batterman, a public-spirited merchant of Brooklyn, has notified the trustees of the Bushwick and East Brooklyn Dispensary, that he is prepared on demand to give them an unconditioned gift of \$25,000 in memory of his dead daughter. Upon receipt of the news the trustees at once selected a committee to obtain plans for a new dispensary building. The present one is located at the corner of Lewis and Myrtle Avenues and consists of buildings that were formerly frame residential property.

Result of Examinations taken before the Illinois State Board of Health during the years 1895, 1896 and 1897 by physicians required to supplement their diplomas by examination, by non-graduates and midwives:

1895. Supplemental, 45; passed, 24; failed, 21. Non-graduates, 35; passed, 13; failed, 22. Midwives, 108; passed, 42; failed, 66. Total passed, 79; total failed, 109.

1896. Supplemental, 13; passed, 9; failed, 4. Non-graduates, 36; passed, 14; failed, 22. Midwives, 102; passed, 30; failed, 72. Total passed, 53; total failed, 98.

1897. Supplemental, 35; passed, 27; failed, 8. Non-graduates, 41; passed, 12; failed, 29. Midwives, 77; passed, 50; failed, 27. Total passed, 89; total failed, 64.

Total for three years: Passed, 221; failed, 271.

Kryofin, an Antipyretic.—A new antipyretic, an analogue of phenacetin, is under trial in Germany and Switzerland. It is a para-phenetidin derivative, being the condensation product obtained from heating that substance with methoxyacetic acid, phenacetin being an aceto-para-phenetidin. Dr. Hermann

Eichorst says this is the most reliable antipyretic with which he is acquainted. This conclusion was arrived at after careful test by Dr. Bischler at the medical clinic of the University of Zurich. Kryofin forms white, odorless crystals, which have no taste, and are, therefore, conveniently taken in powder form or in wafers. It is soluble 1 to 52 in boiling, and 1 to 600 in cold water. In concentrated solution kryofin tastes bitter and biting. A reliable active dose is seven and a half grains. —*Deutsche Med. Wochenschrift.*

Introduction of the Crookes' Tube into the Natural Cavities for Radiography.—The *Presse Méd.*, March 9, reproduces some radiographs taken with a long and slender Crookes' tube inserted in the vagina (Destot diaphragm Crookes' tube). The harmlessness of close contact of the tube with the tissues was carefully tested beforehand by personal experiences, by L. Bouchacourt, who states that "no after-effects follow the use of the static machine in the place of the Ruhmkorff coil, as has been demonstrated by Destot, Free of Chicago and Monell of New York." The tube was inserted within a wooden speculum or tube, with an adjustable cap at the distal end. The rays started from a point not far from this end and the patients radiographed did not feel the electricity at all, at any time during the ten to thirty-five minute tests and exposures. No after-effects have been perceived during the month since. The positive pole was in contact with the ground, with which the patient was also in contact. The body therefore served only as a support and no sparks nor sensations of any kind were experienced. Bouchacourt suggests that special tubes and instantaneous exposures may result in radiographs taken with the tube in the esophagus, trachea or other cavities, while the buccal cavity, the rectum and the vagina can already be radiographed in this way.

Pathology of Epilepsy.—N. Krainsky of Charkow asserts that there is a close and constant connection between the excretion of urea and epilepsy. Every attack is preceded, twenty-four to forty-eight hours, by a diminution in the amount of urea excreted, and as long as an epileptic excretes 0.6 to 0.8 urea during the day there is no danger of an attack, but if the excretion falls to 0.45 or 0.35, one is imminent. He therefore suggests that epilepsy instead of being a purely nervous affection may depend upon anomalies in the metabolism. Attempts to influence the excretion of urea with piperazin and lysidin were ineffectual, but lithium carbonicum, 1.0, three times a day, produced a decidedly favorable effect. Animals injected with the blood of epileptics drawn during an attack were affected with paralysis and periodical attacks, terminating fatally in four to eight days. As injections of carbamic acid ammonium produced exactly similar effects, Krainsky is inclined to ascribe the attacks to an accumulation of this salt in the organism. During the attack it is transformed into urea and water. This assumption harmonizes with the known favorable effect of potassium and sodium bromid, as they form with it the harmless potassium and sodium salts of carbamic acid. —*Wien. klin. Woch.*, February 24.

The Laporte Case.—The French supreme court of appeals has reversed the decision of the lower court condemning Dr. Laporte to three months imprisonment—the particulars were given in the *JOURNAL* at the time, Nov. 13, 1897, page 1029—considering that the extenuating circumstances were sufficient to free him from penal responsibility. Commenting upon the lack of suitable gynecologic instruments which was the primary cause of the fatal lesions in the case, a writer in a Paris daily urged that the public authorities ought to equip young physicians with proper instruments for the practice of their art, at the public expense: "We spend millions to supply our young soldiers with all the latest appliances to *destroy* life, and not a cent goes to the infinitely more important work of equipping our young professionals to *save* life." As a con-

sequence of this affair many physicians summoned to a case of difficult delivery shrink from assuming the responsibility, and on one pretext or another decline to attend. Professor Pinard thus relates a case in which the patient sent for seven physicians in turn without securing one, and was finally carried to the hospital at 11 P.M., dying before morning, which he thinks would not have occurred if prompter measures could have been applied.

The Siphon Drainage of Large Cavities.—Heaton describes a familiar apparatus for the continuous siphonage of the contents of large cavities, with an important modification. As is well known, siphonage is commonly seriously interfered with by the sucking of the soft walls of the cavity against the openings in the rubber or glass tubes employed, and consequent interference with the action of the siphon. Heaton has employed with success an outer perforated tube, and an inner tube which is connected with the siphon. Fluid trickles into the outer tube through the perforations and is then sucked up through the open end of the inner tube. This apparatus has answered its purpose well in six cases in which it has been employed. —*British Medical Journal.*

Abstinence from Alcohol in Hospitals for the Insane.—Dr. Schlangenhäuser of Villach, writing to the *Lancet*, March 5, refers to the views of German alienists as expressed at their recent convention at Hanover, regarding the rôle of alcohol in hospitals for the insane. This subject of the employment of stimulants in asylums was discussed by Dr. Hoppe of Allenberg, who concluded his discourse by expressing the opinion that alcohol should not only be kept out of the reach of drunkards by establishing in asylums a so-called drunkards' department, but should be kept altogether out of asylums, milk or lemonade being substituted for it. "If alcoholists," contended Dr. Hoppe, "were not to be allowed to have alcohol, then the other patients should also not be allowed to have it, as otherwise it would be impossible to make alcoholists practice total abstinence." The greater portion of the alienists present were in favor of Dr. Hoppe's views; and some of these alienists, amongst others Forel of Burghoelzli, and Mocli of Berlin, have already introduced the system of total abstinence into the respective asylums of which they are the medical superintendents. At this convention was passed a resolution directed principally against a criticism contrary to facts on the part of the Reichstag in January, 1897, having reference to the actual condition of German asylums. This resolution is as follows: "This meeting concurs in the proposal adopted at the sitting of the Reichstag for regulating in conformity with the laws of the empire the supervision of lunatic asylums. But this meeting considers it a duty to point out once more that the most important reform consists in the establishment of independent boards of supervision directly subordinate to the minister and at the head of which stands a specialist occupying that post at headquarters."

What Is Fame?—A correspondence, which doubtless will be highly amusing to Mr. Frederic Treves, is at present in progress in the pages of the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*. Two practitioners have been and are discussing the subject of appendicitis and its treatment, and they differ. In a recent communication one of them in support of his contention aspired to silence his opponent by quoting Mr. Treves. But the effect was scarcely that which was expected. The opponent retorted by saying "my friend quotes Treves and Thalamon, both of whom had limited experience with the operation of appendicitis, and whose opinions should not count alongside of such men as Robert Morris, J. B. Murphy, Joseph Price, Fowler and Deaver, men who have had hundreds of operations and seen the terrible results of procrastination." Again, the writer adds, "my friend will accept the dictum of a general surgeon with a very limited experience

in abdominal surgery, like Treves, or some young man, also with a quite limited experience, like Thalamon, while I prefer the views of men who have operated on a couple of hundred cases each, like Price, Deaver, Murphy, Fowler, Morris and others." After this, English surgeons who have ventured to admit that they have operated upon appendicitis cases will have to hide their diminished heads. In passing, however, it might be observed that if the capacity of a surgeon is merely one measured by the numerical index of his operations, then competition with a "great country" like America is quite impossible. But it is worthy of note that soon after appendicitis was discovered it became in the United States a new disease. Judging from the literature upon the subject, we suppose that it has since become hereditary: for to be fashionable in America everyone must have had appendicitis and have been operated upon.—*Med. Press and Circular*, London, March 9.

Version Extraordinary by Ramsbotham.—The *Reminiscences* of the venerable Dr. Robert Barnes of London, as given by him in current issues of the *Scalpel*, afford us the following anecdote: My recollections of the London Hospital are pleasant. I was elected assistant obstetric physician in 1859, and so had at first to serve under Dr. Ramsbotham. We worked very well together, but he continued to hold office longer than was expected. I may relate one instance, illustrating the anomalous position in which the obstetric physicians were held. A case of gestation, demanding delivery by Cæsarian section, occurred. Obviously this was an obstetric case, but under the surgical law, delivery requiring the knife was within the right or duty of the surgeon. Ramsbotham and I had to look on while the surgeon operated. The surgeon laid open the abdomen, laid bare the gravid uterus, made an ample incision in it. The fetus came into view, its long axis corresponding to the long axis of the uterus. He seized an arm, dragged it, expecting to lift the fetus easily out of the uterus. He was foiled, but tugged at it till uterus and fetus together came through the abdominal wound. At this crisis Ramsbotham had to intervene and do the obstetric work. He put the arm back, by a delicate maneuver, seized a foot, and holding this with one hand, whilst he applied counter-pressure with the other hand upon the head and upper part of the trunk, he turned, and extracted the child with the greatest neatness and ease. A more beautiful and artistic demonstration of the problem of turning than this completely visible performance it is impossible to imagine. One thing it proved was that the surgeon was not qualified to practice obstetrics.

Sexual Origin of Neurasthenia and Psychoneurosis.—Sigmund Freud announced a while ago that every case of psychoneurosis, fixed ideas, etc., had for its predisposing cause some abnormal occurrence in the sexual life before the age of eight years, consciously or unconsciously remembered. He now asserts that every case of neurasthenia has a similar basis, some abnormal occurrence or occurrences in the sexual life of the patient at the present time or since puberty. He scouts the idea that mental overwork or excess of household cares can alone induce neurasthenia, although any depressing factor may favor its development. He even insists that absorbing occupations, especially intellectual, protect against the evolution of neurasthenic affections. He divides them into: 1. Neurasthenia proper, which he claims can always be traced to excessive masturbation, unnatural sexual intercourse, etc. 2. "Anxiety neurasthenia," distinguished by dread, restlessness, agoraphobia, vertigo in walking, sleeplessness, etc.; this form he states can also invariably be traced to sexual influences in the nature of unsatisfied impulses, coitus interruptus, abstinence with inflamed desires, etc. He protests against the prevailing hypocrisy in regard to sexual matters, and urges the physician to assume an abnormal sexual life as his guiding star in the etiology of neurasthenia,

as this alone will help him to treat it rationally, after winning his patient's confidence. In cases absolutely impossible to trace to any abnormal sexual occurrences, he decides that the affection is not neurasthenia, and by eliminating this conception he has discovered unsuspected local affections, in one instance a latent suppuration in one of the accessory nasal cavities, which had only produced neurasthenic symptoms, entirely cured by an operation.—*Wien. klin. Woch.*, 1898, Nos. 2, 4, 5 and 7.

Untutored and Barbarous Medical Practice in the Orient.—It is estimated that exclusive of medical missionaries who are sent to uncivilized lands there is only one qualified physician to every two or three millions of the peoples of Asia and Darker Africa. The following are some of the heathen conditions and practices mentioned by missionaries in their reports: "Eighty families with smallpox in one street in a Burmese city and no physician attending them." "A prescription given by a Chinese physician with the remark: 'This contains so many ingredients that it will cure anything,' and numbering among these twenty ingredients a centipede, a scorpion, a horned toad and a beetle." "A Chinese girl, on entering a foreign hospital, reported having taken by prescription 200 boiled spiders, besides serpents' eggs." "Bricks piled on a broken leg to keep down the swelling." "Babies stuck all over with red hot needles till hardly an inch of unpunctured skin remained." "A man coming for help to missionaries in Africa dragging a broken limb, no surgeon to set it." "Women in India, in their direst need, driven out of the house and left alone or given over to the care of ignorant, superstitious women of the lowest caste."

Cleanings.—Soothing and healing effect of mentholized colloid in extensive contusions of the soft parts, highly lauded in the *Tribuna Méd.*, December 30, 1897.—Several cases of hydrops universalis accompanying malaria cured with antimalarial treatment (*Wien. klin. Woch.*, February 24).—Copious hemorrhage and extensive iridodiolysis during an operation for cataract; recovery (*Tribuna Méd.*, December 15).—Twenty-one cases of puerperal tetanus on record since 1890; only one recovery. First symptoms are trismus and difficulty in swallowing (*Arch. f. Gyn.*, liv, 1).—Case of combined migraine, unilateral paralysis of the cervical sympathetic and Basedow's disease in a woman of 38 years, showing the importance of vasomotor disturbances in the pathogenesis of the latter. Migraine appeared first at 17 years (*Deu. Med. Woch.*, February 17).—Typical case of Addison's disease cured with suprarenal extract and capsules, reported by Bécclère. No recurrence in three years since (*Presse Méd.*, February 26).—Widal and Nobécour have confirmed the antitoxic properties of the nerve centers in the case of strychnin intoxication, already established by Wassermann in regard to tetanus, although with less positive results (*Ibid.*, vide JOURNAL, February 19, page 449).—Absolute failure of serodiagnosis in fatal typical typhoid fever in an epileptic (*Ibid.*).—Delezenne asserts that peptone, usually harmless, injected into the veins of a dog becomes fatally toxic, producing paralytic manifestations if heated to 120 degrees C, although still retaining its marked coagulating properties (*Ibid.*).—Cracked nipples successfully treated without inconvenience to the mother or nursing with the assistance of orthoform (*Ibid.*).—Sage of Bordeaux reports the first case in France of the birth of a healthy child at term, the mother having commenced to menstruate at 12 years and eight months, and conception occurring one month later, delivery at thirteen and a half (*Sem. Méd.*, February 9).—Negative results of lumbar puncture in chronic hydrocephalus reported by Raczyński; twenty-six cases. Slight transient relief was obtained only in five cases consecutive to epidemic meningitis (*Przegląd lekarski*, 1897, 33).—Inflammation of the navel and penis in an infant after circumcision, found to contain the Loeffler bacillus, and cured with antidipteria serum (*Ibid.*, 51).—The intensity of the mercurial treatment required in syphilis varies not only for each individual, but for different lesions on the same individual. Instance reported in which hypodermic injections of five centigrams

calomel promptly cured all the lesions except one on the lip, which was not affected by the treatment until the dose was doubled, when it also vanished (*Ann. de derm. et de Syph.*, February).—Case of pulmonary gangrene consecutive to ether narcosis reported by Dumas, in patient affected with chronic bronchitis (*Journ. de Méd. Int.*, November, 1897.)

British Army Medical Department Report for the Year 1896.—The strength of the European troops of the British Army serving at home and abroad in 1896 was a little over 200,000 men, of whom rather less than one-half were on duty at the home stations; 75,000 served in India, 8000 in Malta, 4000 each in Gibraltar, Egypt and South Africa, with smaller commands in various other parts of the world. The rate of constant sickness for the whole army was 60.71 per thousand men, with 8.14 deaths and 16.26 discharges for disability. The average sick time to each soldier was 22.22 days and the average duration of each case of sickness 23.61 days. Among the troops serving in the United Kingdom the rates of sickness and mortality were lower than usual. The constant sickness was 38.52 per thousand of strength with 3.58 deaths and 21.20 discharges, the average sick time to each soldier being 14.10 days and the average duration of each case 21.85 days. Our United States rates for the same year, with the exception of the death rate, were considerably lower than these. We had 33.97 constantly sick, with 5.44 deaths and 10.15 invalided per thousand of strength, the sick time to each man being 12.43 days and the duration of each case 11.19 days. As regards the smaller death rate of the British home service, it is to be observed that if men suffering from such a disease as consumption are promptly discharged the death rate is lessened at the expense of the rate of invaliding. Not the death rate alone, but the death rate added to the discharge rate, is the measure of the disabling character of the sickness affecting an army. The admissions for enteric fever numbered 94 and the deaths 22, an exceedingly high rate of fatality, but the mortality rate per thousand of strength was low, .21 as compared with our rate of .63. At Pembroke Dock there was a well marked outbreak. The water closet, sink and bath of a building in which a fever case was undergoing treatment, emptied into a common drain beneath which was a lead pipe, corroded and leaky, supplying drinking water to the hospital. Twenty cases with two deaths occurred among persons using the hospital water-supply; and the last case was taken on sick report seventeen days after the condition of the water-supply pipe was discovered and remedied. The occurrence of 806 cases of malarial fever and 2 deaths from remittent fever is accounted for by "the return of troops from service abroad." The only reference to malaria of indigenous origin is found in a remark on the sanitary condition of Lincoln: "A few cases of ague, due to local causes, were noted during the year." The fens of Lincolnshire, as is well known, were in former times the headquarters of the malarial parasite in England. The constant sickness from all forms of venereal disease was 13.94 per thousand of strength as compared with 5.26 in the U. S. Army.

The number of recruits inspected during the year was 54,574, of whom 423.48 per thousand were rejected as unfit for service; the rejections during the same year by U. S. recruiting officers were 371.65 per thousand examined. Nearly one half of the accepted recruits were under 19 years of age; 1372 were boys under 17 years of age. Omitting these boys the average age of the recruits was 19.3 years, the average height 5 feet 5.9 inches and the average weight 125.8 pounds.

The highest rates of constant non efficiency from sickness among troops serving abroad were 93.85 per thousand of strength in India and 87.57 in China; the lowest 26.86 in Bermuda and 28.36 in Canada. The lowest rate of discharge for disability was 31.29 in China, with 61.22 sent home as invalids. The longest sick time to each soldier of the command was 31.35 days in India, the shortest 9.83 in Bermuda. No yellow fever was reported during the year from Barbadoes or Jamaica, and only six cases of cholera occurred among the troops in Alexandria and Cairo, Egypt, although the civil population suffered severely. Both cities were placed "out of bounds" during the prevalence of the disease.

In India there was an increase in the sickness from enteric fever, other continued fevers and cholera; malarial fevers accounted for one-fifth and venereal diseases for one-third of

the reported cases of sickness. Enteric fever caused 1795 admissions into hospital, or 25.5 per thousand of strength, with 445 deaths, or the very large death rate of 6.31. The largest number of cases occurred at Quetta, 140 admissions with 22 deaths. The water-supply of this station is brought in pipes from an uninhabited mountain district thirteen miles distant. The febrile outbreak was attributed to exposure in the insanitary brothels and drinking shops of the neighboring native town. At some of the posts the type of the disease is said to have been very severe, as although the sufferers were very young men, their constitutions had already been undermined by syphilis, and their chances of recovery thus greatly lessened. The pinking of the water-supply by potassium permanganate was employed as a preventive measure at several posts during the outbreak, but without satisfactory results. In fact, at Agra enteric bacilli were found in a flourishing condition in the pink water. "This," says the reporter, "was a great disappointment to me, as I was beginning to think that a panacea had been found for this scourge. The situation was now desperate, so after consultation with Professor Hankin, we commenced making experiments with micrococcus ghadii, found by him to be antagonistic to the enteric microbe. This micrococcus is quite harmless to human beings, so I had no hesitation in trying it as the enteric cases were increasing daily. It was first tried at the swimming bath at the Fort, which was found to be infected with the enteric microbe. In four days there were none. About the same time it was taken into use at the Agra Club; then the water supply at the Fort was treated, with an almost immediate cessation of cases, and lastly the water of the whole cantonment, and the disease at once began to ameliorate in a very marked manner. From the time the water-supply was treated with the micrococcus the number of admissions fell rapidly. I have not been able to follow out the research desirable in this line, as Professor Hankin has left the station for the purpose of investigating the plague at Bombay, and I am thus deprived of his assistance. The matter is, I think, well worth further investigation." Of the several measures adopted for sterilizing drinking water, with a view to the prevention of water-borne diseases the most efficient was boiling. Cholera caused 70 admissions and 63 deaths during the year. The constant sickness from malarial fevers numbered 10.15 per thousand of strength. The admission rate for venereal diseases was 511.6 per thousand and the constantly sick 44.87, representing a loss of 3162 men to the efficient strength of the Indian command. The hypodermic injection of mercury was freely resorted to with excellent results. "This treatment enables many men, who would otherwise be in hospital, to perform their usual duties; it brings the patient more quickly than the old method under the influence of the drug and does not derange the digestion." The result of the voluminous discussions in and outside Parliament on venereal diseases ended in the promulgation of the amended Cantonment Act, which gives greater power to local authorities over the prostitute population, but falls short of the registration and periodical examinations which many experienced officers advocated. It is noted that no case of bubonic plague occurred among the garrison of Hongkong, although more than 1100 of the native population died of this disease.

Several valuable papers are appended to this report, among others a résumé of the progress of hygiene during the year 1897 by Surgeon Colonel J. Lane Notter, who gives a summary of Prof. V. C. Vaughan's paper on the prevention of tuberculosis, read at the Twelfth International Congress of Medicine, and discusses the progress made in sewage disposal by biologic methods at Exeter and Sutton. A paper on the operations performed at the Royal Victoria Hospital, neatly illustrated by some good skiagraphs of fractured bones. Surgeon-Lieut.-Colonel, J. A. Gormley reports on the operations of the forces in Southern Africa, and Major-General T. Mannsall, C. B., gives an interesting account of the difficulties experienced by the medical department in the Chitral Relief Expedition. The emergency ration known as "Armebis" was condemned as not being safe. Many of the tins "went bad," and one man nearly died with symptoms of ptomain poisoning after eating the contents of one. Even when good the biscuits were a possible cause of diarrhea owing to imperfect milling of the envelope of their wheat constituent. Lieut. D. W. Sutherland gives the particulars of a number of cases of wound by the Lee-Metford rifle bullets. These wounds were generally characterized by slight shock, slight pain, free hemorrhage, simple perforation of bone and rapid healing. The natives reported that those shot in the head died at once on the field; those wounded in the abdomen often died on the field, but some reached their homes to die a few days later; all the others recovered promptly. Surgeon-Lieut.-Col. A. T. Sloggett reports on the Dongola Expedition, the chief medical interest of which centers in a

typhoid fever epidemic and an invasion of the Command by cholera. A full account of the proceedings of the Seventh Annual Session of the Association of United States Military Surgeons held at Columbus, Ohio, in May, 1897, is given by Deputy Surgeon-General W. S. Oliver, and a report on the Twelfth International Medical Congress held at Moscow in August, by Surgeon-Colonel W. F. Stevenson, in which he gives prominence to Surgeon-General Van Reyden's proposition for a hospital or ambulance ship in the care of the wounded of modern naval wars, and to Surgeon-General Sternberg's report on operations for the radical cure of hernia in the United States Army.

Decision Concerning Osteopathy.—The following is a decision concerning osteopathy, by District Judge H. H. Rolapp, of Utah.

State vs. William Hartford: The defendant is charged by an information with practicing medicine without a license from the State Board of Medical Examiners.

Section 1736 of the Revised Statutes provides that "Any person practicing medicine . . . within this State without holding . . . a license shall . . . be deemed guilty of a misdemeanor."

Section 1737 provides that "Any person shall be regarded as practicing medicine within the meaning of this title who shall treat, operate upon, or prescribe for any physical ailment of another for a fee."

The defendant admits having manipulated with his hands upon persons for physical ailments, for a fee, and without a license; but insists that inasmuch as he uses no medicine or surgical instruments, or any other agencies except his naked hands, that he does not come within the prohibited class named in the statute. He does not hold himself out as a doctor, physician or surgeon, but denominates himself a diplomat of osteopathy. He further insists that his science does not belong to any recognized school of medicine; or, if it does, that the present State Board of Medical Examiners is not legally constituted, it being admitted that no osteopathist is a member of such Board—while Section 1728 of the Revised Statutes provides that said Board "shall consist of seven members, who shall be representatives of the various recognized schools of medicine."

The latter point, I apprehend, can not be determined in this case. The whole inquiry, then, recurs to whether the defendant is practicing medicine within the meaning of the act.

Counsel for defendant invites attention to the case of *Smith vs. Lane* (24 Hun., 632) which seems to be in point, if the statutes upon which that decision was founded were as broad as ours. But in the New York statute it is simply provided, in specific terms, that the practice of medicine or surgery should be a misdemeanor, unless authorized by a certificate setting forth such person's qualifications to practice all of the branches of the medical arts. Under that provision it was undoubtedly the duty of the Court to interpret the words "practice of medicine and surgery" in the common acceptance of those words; and they therefore said "the practice of medicine is a pursuit very generally known and understood, and so also is that of surgery. The former includes the application and use of medicine and drugs for the purpose of curing, mitigating or alleviating bodily diseases; while the functions of the latter are limited to manual operations usually performed by surgical instruments or appliances."

That is undoubtedly a good definition of the words in the statute then before the Court. But our statute goes farther, and says that, "any person shall be regarded as practicing medicine . . . who shall treat, operate upon, or prescribe for any physical ailment of another for a fee." The word "treat" as defined by Webster, in this connection, is synonymous with "manipulation," "handling," "mode or manner of checking and destroying disease." That is exactly what the testimony in this case shows the defendant did; and the legislature must have intended that the words thus used by them should have some significance, and be used in connection with "ailments." There is no suggestion in the section that the word "treat" referred to treating with medicine, or with any other specific agencies of a similar kind. If such treatment was done by the naked hands and for the purpose of curing ailments of another, and was done for a fee, it seems to come logically within the intention of the statute, which defines such treatment, handling or manipulation as practicing medicine. That the section is sweeping, I admit; but the power of the legislature to thus enact is undoubtedly possessed.

My attention was also called to the case of *State against Eastman*, decided in Indiana. While I can not fully concur with the learned judge in the interpretation placed upon the statute then under consideration by him, yet all he suggested

was that the words "other agencies," named in that statute, referred to drugs and medicines, and as osteopathy does not include the use of such agencies the practitioners of that science did not come within the prohibition of that statute. Granting the premises in regard to the interpretation of the statute, of course the conclusion was right; but in addition to that the Indiana statute only prohibited the direction or recommending for use by another of drugs, medicines or other agencies, but said absolutely nothing about the personal treatment by a person upon another for the curing of ailments. Such treatment is directly covered by our statute.

I think the decision in *Illinois*, in the case of *Eastman against The People* is the most valuable, because it concerns itself with a statute identical with ours. Says the court in that case: "It appears that the appellant was engaged in the practice of 'the profession of osteopathy' as it is termed in the briefs; that he had an office where he received patients, and that he visited patients at their homes; that he advertised his system and his skill therein, and that he professed ability to understand and treat human ailments intelligently and successfully. So far as shown his treatment consisted wholly of rubbing and manipulating the affected parts with his hands and fingers and by flexing and moving the limbs of the patient in various ways. It is insisted on his behalf that because he used no medicine or instruments he is not amenable to the statute, which reads: 'Any person shall be regarded as practicing medicine within the meaning of this Act who shall treat, operate on or prescribe for any physical ailment of another.' It is urged on behalf of the appellant that this provision must receive a reasonable interpretation and to 'treat' implies the use of medicines or drugs of some sort. This is not so necessary. Many of the minor operations are effected without the use of instruments by mere pressure, extension and flexing. This of course implies some knowledge of anatomy and some skill. It is said by counsel that if the statute reaches this case, it must include treatment by Turkish baths, massage and the like. We think not. The evidence shows that the appellant claimed to be competent to treat and cure numerous diseases. He represented himself as a graduate of the new school of osteopathy and qualified to examine and treat all who might seek his aid. Herein he differs from those who give Turkish baths, massage and the like. He professes to be able to diagnose and advise in respect to a long list of diseases, and to furnish discriminating and efficient treatment to those who may come to him, and while he may rely wholly upon manipulation, etc., yet he professes to have skill and judgment in these methods so as properly to adapt the treatment to each case, giving it what is appropriate in amount, and with repetition at such times and to such extent as may be dictated by his knowledge and experience. By his skill in the use of his peculiar remedy or methods he claims to be competent to relieve and cure various ailments, and therefore he invites patronage.

"Medicine is the art of understanding diseases and curing or relieving them when possible. It is that branch of physics which relates to the healing of diseases. This art is not restricted to any particular methods or remedies. These are innumerable, considering what are used and have been discarded. We are of opinion the proofs bring appellant within the Act and that he is liable to the penalty imposed for practicing medicine without a license."

I think the same reasoning applies in the case at bar.

A number of other questions were raised at the trial, but I consider it wholly immaterial whether the legislature of Missouri has declared osteopathy not to be the practice of medicine, because that does not bind our legislature. Nor can I consider here the benefit the defendant may have been to the citizens of this community (which fact I do not doubt), or that the medical fraternity are the instigator of this prosecution.

The legislature is the proper tribunal that should be applied to in permitting the engaging in any science or art that will be of benefit to humanity; but until they do, or while they have specifically enacted laws to the contrary, I am simply called upon to interpret the law as I find it; and I can come to no other conclusion than that the treatment or manipulation engaged in by the defendant requires him to take out a license. Having failed to do so he has violated the statute. I must therefore find the defendant guilty as charged.

Louisville.

SOCIETY.—The Kentucky Midland Medical Association held its ninth quarterly meeting on April 14. The following program was observed: "Acute Nephritis," J. R. Ely of Frankfort; "Cholera Infantum," S. J. Anderson of Midway; "Gonorrhea," U. V. Williams of Frankfort; "Surgery of the Uterus and Adnexa, per Vaginam," W. H. Wathen of Louisville;

"Ether Anesthesia in Subjects Suffering from Bronchitis," Thad. A. Reamy of Cincinnati; "Asthma," J. M. Rees of Cinthiana; "The Serum Test of Typhoid Fever," D. J. Healey of Lexington and C. C. Lewis of Stamping Ground; "Quinsy and Its Treatment," J. A. Stucky of Lexington and J. M. Ray of Louisville; "Obstinate Neuralgia of the Mastoid," Robert Sattler of Cincinnati and John E. Pack of Georgetown; "Acute Nephritis," C. W. Kavanaugh of Lawrenceburg; "Cholera Infantum," T. M. Beard of Shelbyville; "Gonorrhea," John C. Lewis of Georgetown; "Surgery of the Uterus," Louis Frank of Louisville; "Ether Anesthesia," T. H. Willis of Shelbyville; "Asthma," S. E. James of Frankfort. Dr. W. E. Sleet, President, Medway, Ky. Dr. J. B. Powers, Secretary, Lawrenceburg.

MEDICO-CHIRURGICAL SOCIETY.—The regular meeting of this Society was held on the 8th of April, as the guest of Dr. Wm. Bailey, the title of whose essay was "The Inadequate Kidney."

GRANT.—Dr. H. Horace Grant is quite seriously ill as the result of septic inoculation at an operation.

HEALTH OFFICE.—The weekly death report shows 54 deaths, the greatest number, 5, being due to phthisis. Thirty-seven were white, 17 colored, 34 males and 20 females. Typhoid fever caused 4 deaths.

Cincinnati.

AT THE REGULAR MEETING of the Academy of Medicine April 4, Dr. H. W. Bettman read a paper on "Enteroptosis." The author's studies and measurements were taken from hospital cases during a period of over two years. The discussion showed the opinion of the society to be against the establishment of this trouble as a clinical entity, and especially against the stand taken by the author of the frequent accompanying ptosis of the right kidney. Dr. Joseph Ransohoff reported a case of inguinal hernia operated on by him, in which on opening the sac a milky fluid to the amount of about a pint, apparently from the abdominal cavity, escaped. The examination of the fluid showed it to be chyle. There were no symptoms of any trouble with the thoracic duct and the ascites had not been of sufficient quantity to attract the attention either of the patient or his attending interne. On the contrary, he seemed to be in the best of health, entering the hospital only to have his hernia operated upon.

THE CHANGES in the administration of city affairs will undoubtedly result in the deposition of Dr. John M. Withrow, one of the most competent health officers the city has ever had. Though serving but a short time he will be held in grateful remembrance for his untiring efforts in quarantining the city against yellow fever last fall, and especially for his recent active crusade against diphtheria and consumption. His map of the city illustrating the prevalence of these two diseases, show that contrary to general opinion the heart of the city, by far the most densely populated, is the most healthy as far as these two diseases are concerned, and that cases are far more numerous along the river and in the outlying districts.

THE CINCINNATI HOSPITAL will show that admissions for treatment were far less numerous in 1897 than the previous year by over four hundred; this falling off is not due to less applications but to a more rigid system of examination and inquiry as to their circumstances and right to the city's charity.

THE PHYSICIANS of Campbell County, Ky., just across the river, have volunteered their services to the medical director of the G. A. R. encampment for use during the meeting here of September next.

Detroit.

WAYNE COUNTY MEDICAL SOCIETY.—At the regular meeting of this Society held on April 7, Dr. E. D. Rice of Flint, Mich., read a very able paper on "The Physiological Functions of the Liver and their Relations to the Digestive Process." The Doctor reviewed the histology and physiology of the liver, and

showed how intimately the disturbances of this organ are connected with the disturbances of the stomach and duodenum. The most interesting function of the liver referred to by the author is the power it has of eliminating toxins from the system, produced in the intestinal canal or by the process of metabolism in any part of the body. Dr. Fritz Maass, illustrating the wonderful resistance of this organ to disease, recited a case recently occurring under his own observation. The patient was a man of 50 years; previous history negative; had been suddenly, while in apparent good health, seized with a severe pain in the region of the liver. The attending physician ascribed the pain to gall-stones and administered a hypodermatic injection of morphin, which relieved the suffering at once and the man returned to his work. In exactly eight days the pain returned and was again relieved by the needle. This was repeated in another week; but at the fourth attack, some twenty-one days after the first attack, the pain was more agonizing and the morphin failed to relieve. Chills, fever and unconsciousness supervened and the man died. At autopsy the liver presented no apparent evidence of disease sufficient to cause death, the stomach and bowels appeared healthy, a few very small gall-stones were found in the gall-duct, and there was a slight congestion of the meninges of the brain. Blood from the heart and sections of the liver were preserved and from these cultures were made. Streptococci in pure cultures were found in abundance from both the liver and the blood, leading to a diagnosis of pyemia with origin in the liver.

HEALTH REPORT for the week ending April 8: Number of cases of diphtheria remaining, 2; scarlet fever, 14; total deaths, 103; under 5 years, 37; births, male 42, female 46.

Philadelphia.

STUDENTS AND THE WAR MEDICAL STUDENTS who are about to graduate at the University of Pennsylvania are clamoring for early final examinations in order that they may enlist in the hospital corps of the army and navy should their services be needed in a war with Spain. Dr. M. T. Stout, who formerly served in the United States Navy, recently put the question to the class as to how many would enlist in the hospital corps and two-thirds of the class stood up. The source of inspiration in the movement is to avenge the sad death of Osgood the athlete of the University who lost his life in Cuba battling for Cuban independence. Professor John Guit  ras, lecturer on pathology at the University and a prominent leader in the Cuban junta, is watching the enthusiasm of the class with much gratification.

CHARITY ABUSE IN PHILADELPHIA.—At a meeting of the Medical-legal Society of Philadelphia plans were discussed relative to influencing legislation to regulate the use of free hospitals by the community at large. The object of the society is to first organize the medical profession through the influence of the County Medical Society and afterward the State Medical Society. Another meeting will be held this month and recommendations presented looking to the introduction of the subject into the County Medical Society. Dr. J. H. Dripps is president of the society.

VACCINATION SAID TO HAVE CAUSED DEATH.—Alice Dempsey, a girl six years of age, was recently vaccinated and it is said that septicemia subsequently developed from the effects of which she died a few days later at the Germantown Hospital.

THE TRUSTEES of Jefferson Medical College have divided the chair left vacant by the death of Professor Parvin and have elected Dr. E. E. Montgomery professor of diseases of women and clinical gynecology and Dr. E. P. Davis professor of obstetrics.

A CASE of smallpox of mild type and unknown origin was discovered in this city early last week and at once removed to the Municipal Hospital and the premises disinfected. The city had been free from this disease since 1895 and has had no epidemic of smallpox for nearly ten years.

THE TRUSTEES of the Medico-Chirurgical College have petitioned the State legislature to amend their charter so that they may add a department of pharmacy as well as a department of dentistry, and become duly authorized to confer the degree of graduate in pharmacy as well as that of doctor of dental surgery and of medicine.

THE PROPOSED Health Protective Hospital, or pay hospital for contagious diseases, it is hoped will soon be an accomplished fact, as active efforts are being put forth to obtain the much-needed funds for ground and buildings. Dr. J. Madison Taylor is treasurer and Judge William N. Ashman president of the board of trustees.

THE POLYCLINIC HOSPITAL and School for Graduates in Medicine announces a week in diagnosis, beginning May 9. Lectures and demonstrations in the clinics and laboratories of the Polyclinic on various special topics, including the Clinical Use of the Microscope, Chemic and Bacteriologic Methods and X-Ray Examinations, it is thought will interest experienced practitioners as well as recent graduates. Dr. Charles K. Mills has been elected to the newly created chair of neuro-pathology, having resigned from the chair of nervous diseases, which was abolished.

Washington.

HEALTH OF THE DISTRICT. The report of Health Officer Woodward for the week ended April 2, shows the total number of deaths to have been 93, of which number 52 were white and 41 colored. Among the principal causes of death were: nervous diseases, 14; circulatory, 7; genito-urinary, 10. One death from diphtheria and one from whooping cough. A case of smallpox was reported at Freedman's Hospital. The patient, a colored boy, aged 20 years, left Knoxville, Tenn., on the 14th ultimo, and with three companions worked his way to this city on a freight train. He was taken sick on reaching this city and was admitted to the wards of Freedman's Hospital, whence he was removed to the smallpox hospital, after the nature of his disease was determined. There were three cases of smallpox on the "pest-boat" at Knoxville, Tenn., when he left. There were 28 cases of diphtheria and 55 cases of scarlet fever under treatment at the close of the week. The Health Officer has placed Freedman's Hospital under strict quarantine and has carried out the most approved methods of disinfection.

WASHINGTON OBSTETRICAL AND GYNECOLOGICAL SOCIETY.—The 278th meeting of the Society was held on the 18th ultimo, at the residence of Dr. Deale. Dr. H. L. E. Johnson presented the essay of the evening, "Vaginal Hysterectomy for Procidencia," case and specimen. He reported a modification of his own for vaginal hysterectomy in which he combines the clamp and suture methods. The broad ligaments are clamped in the usual way and the anterior and posterior vaginal flaps are stitched to the peritoneum and broad ligament, the flaps being then stitched together. He claims by so doing that subsequent vaginal prolapse would be avoided. An interesting discussion followed. At the meeting held April 1, Dr. E. E. Morse was elected to membership.

SEWAGE DISPOSAL.—Commissioner Black has, in reply to a request by Senator Gallinger, written the latter a brief description of the proposed sewage-disposal system of the District of Columbia, and recommends the reclamation of the Anacostia Flats.

HOSPITALS AT OLD POINT. Assistant Secretary Meiklejohn of the War Department is authority for the statement that the removal of the hotel Chamberlin and the Hygeia hotel is no part of the present project of preparations for the National defence at Fort Monroe, Va. These large hotels were built on the Government reservation at Fort Monroe with the condition that the Government may, without liability for a claim for damages, remove them in case of necessity in case of war. A strong argument for their retention in case of war is that the two large buildings would be of great service as hospitals.

ANNUAL MEETING OF THE DISTRICT ASSOCIATION.—At the regular stated meeting of the Medical Association of the District of Columbia, held on the 2d instant, the following were elected: President, Dr. George M. Kober; vice-presidents, Drs. Cuthbert and L. Elliot; secretary, J. R. Wellington; treasurer, Frank Leech; councilors, Drs. Mayfield, T. R. Stone, Acker, McLain, Ober, Carr, D. O. Leech, H. L. E. Johnson and Holden; censors, Drs. Woodward, Cook and Glazebrook; delegates to the meeting of the AMERICAN MEDICAL ASSOCIATION, to be held in Denver Col., Drs. Heiberger, Stone, H. L. E. Johnson, Crosson, Portman, Moran, Belt, Kober, Koonen, Reyburn, Kleinschmidt, Middleton, Carr, Shouds, Franzoni, Hazen, S. S. Adams, Myers, Huinche, Cook, Brehend, Bovee, L. Elliott, D. O. Leech, Bowen, Mackall, Jr., Wellington, Barker, Fox, J. Eliot, Butler, Glazebrook, Godding, Cole, Hunt, Sillers, J. D. Morgan, Hegar, Duffey and Woodward. The following new members were elected: James T. Arwine, Grafton D. P. Bailey, William T. Burch, DeWitt C. Chadwick, James W. Hart, Isabel Haslup, J. M. Heller, T. Y. Hull, William P. Mills, John B. Nichols, John L. Norris, Jesse N. Reeve, William N. Suter, Joseph S. Wall and William Edward West.

HOSPITAL ABUSES.—A special meeting of the Medical Association was called on March 15, to consider the report of the Standing Committee which has been investigating the matter of Hospital Abuses. The Association is determined that all abuses of this character shall be checked, and after hearing the partial report of the Standing Committee, the following was adopted:

WHEREAS, The object of the amendment adopted by the Medical Association of the District of Columbia, May 16, 1897, is, and always has been to check the growing abuse of Medical Charities in this city, and

WHEREAS, It appears from the report of the Standing Committee that the Staffs of several Medical Charities have not complied with these amendments, be it

Resolved, That the Standing Committee be instructed to notify the individual members of the staffs of such Medical Charities that unless satisfactory evidence be furnished on or before April 1, 1898, that the letter and spirit of these amendments are complied with, the Standing Committee will proceed to arraign the members of the various staffs for violation of these rules, and to report its findings to this Association.

In pursuance of the above, the Standing Committee, through its Secretary has sent to each physician who is connected with one or more hospitals, the following queries, and have requested a prompt reply: 1. Do you require evidence before attending a patient in the medical charity with which you are connected, that the applicant for relief, except in emergency cases, has furnished a certificate as required in Article 1 and 2 of the Amendments of the Medical Association? 2. What are the exact methods pursued by the staff of the institution with which you are connected to limit gratuitous services to the indigent sick? 3. Does the hospital with which you are connected grant you and all other members of the Medical Association the privilege of attending private patients occupying private rooms? 4. Do you, as a member of the medical staff of the Hospital with which you are connected, when attending medical or surgical cases in private pay rooms, insist upon proper payment for your services, except when such patients are clearly unable to pay for the same? Do the Hospital authorities permit you to do this, and what are the methods pursued to sustain your demands?

MEDICAL SOCIETY.—At the meeting of the society held on the 6th instant, Dr. Charles W. Richardson read the essay for the month, entitled "The Acute Mastoid Abscess." The following were elected to membership: Drs. E. Barry, A. W. Boswell, L. A. French, G. W. Foster, M. Griffith, A. B. Hooe, M. D. Magee, H. S. Medaford, M. G. T. Motter, J. B. Nichols, L. S. Savage, W. P. Tucker, J. R. Tubman. The following were elected members by invitation: Drs. A. H. Glennan, Marine Hospital; C. H. White, U. S. N.; J. B. Parker, U. S.

N.; P. Fitzsimmons, U. S. N. A committee consisting of Drs. T. C. Smith, George N. Koeber and W. W. Johnston, recently appointed by the society, read congratulatory resolutions to the president, Dr. Samuel C. Busey, on his completion of fifty years practice of medicine.

DR. BUSEY'S FIFTIETH MEDICAL ANNIVERSARY.—At Dr. Samuel C. Busey's fiftieth anniversary of his graduation from the University of Pennsylvania, Friday evening, April 8, his residence was thronged with admiring friends representing the medical profession, the Senate and House of Representatives, Supreme Court, U. S. Army and Navy and Marine-Hospital Service, eager to extend their congratulations and show their appreciation of the man who stands first in his profession and first in the hearts of all who know him.

Hospitals.

MT. SINAI HOSPITAL, NEW YORK, is a non-sectarian charity that has been in operation as a hospital since June, 1872, at its Lexington avenue site. These quarters have been outgrown and a new plot of land, comprising about twenty-five city lots, has been purchased on 100th and 101st Streets, fronting Central Park nearly the whole block, with the exception of the Madison Avenue front. This plot, very desirably located for hospital purposes, is valued at \$350,000.—The plans for a new medical building at the Johns Hopkine Hospital, Baltimore, have been completed. The physiologic and chemic laboratories will be removed from the university to the hospital grounds. One floor of the new building will be devoted to pharmacology.—By the will of George S. Pepper of Philadelphia, who died in 1890, several hospitals become beneficiaries. The University Hospital receives \$19,750; Presbyterian Hospital \$18,500; Jefferson College Hospital \$18,500; Orthopedic, Charity, St. Joseph's, Children's, St. Christopher's and Maternity Hospitals \$9,250 each. Dr. William Platt Pepper, John S. Gerhard and James B. Leonard, who are the trustees for the estate, report that there is a total increase of the estate since the testator's death of \$199,836.84.

Colleges.

THE MEDICAL COLLEGE of Syracuse University, N. Y., is to receive \$1000 for enlarging the medical library.—The following commencements of medical colleges, with the number of graduates, are noted: April 7, Baltimore University School of Medicine, 54; April 5, Baltimore Medical College, 17; April 4, Birmingham Medical College, 9; April 1, Medical Department State University of Georgia, Augusta, 27; March 28, Missouri Medical College, St. Louis, 85; March 28, College of Physicians and Surgeons, Kansas City, Kan., 24; April 1, Medical College of South Carolina, Charleston, 14; April 5, Ohio Medical University, Columbus, 95; April 6, Iowa College of Physicians and Surgeons, Des Moines, 21.

Relief for Shawneetown Sufferers.—The General Committee appointed by the Hon. Carter H. Harrison, mayor of Chicago, to take measures for the relief of the sufferers from the disastrous flood at Shawneetown, Ill., has selected the undersigned as a sub-committee to solicit aid from the physicians of Chicago. We know too well the kind and charitable motives governing our profession to think it necessary to do more than point out that this calamity which has befallen the unfortunate people of Shawneetown demands immediate relief and we respectfully request that contributions of money be sent immediately to Dr. A. R. Reynolds, Commissioner of Health, City Hall. Checks should be made payable to Treasurer Relief Committee.

Chicago, April 11, 1898.

JOHN B. HAMILTON, M.D.

FRANK BILLINGS, M.D.

J. H. ETHERIDGE, M.D.

CHANGE OF ADDRESS.

Andrews, G. M., from St. Louis, Mo., to Stella, Neb.

THE PUBLIC SERVICE.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from April 2 to 8, 1898.

First Lieut. George Rauchfuss, Asst. Surgeon, resigned April 2, 1898.
First Lieut. Bailey K. Ashford, Asst. Surgeon, the order assigning him to station at Ft. Sam Houston, Texas, is revoked, and he is ordered to Ft. St. Philip, La., for duty at that post.
Capt. Edward Everts, Asst. Surgeon, upon the abandonment of Whipple Bks., Ariz., is ordered to Ft. Apache, Ariz.
First Lieut. Alexander S. Porter, Asst. Surgeon, is relieved from duty at Whipple Bks., Ariz., and upon expiration of his present leave of absence is ordered to San Diego Bks., Cal., for duty.
Capt. Joseph T. Clarke, Asst. Surgeon, is relieved from duty at Columbus Bks., Ohio, and ordered to Madison Bks., N. Y., for duty, relieving Capt. Paul Shillock, Asst. Surgeon. Capt. Shillock, upon being so relieved, will proceed to Key West, Fla., and report to the commanding officer Twenty-fifth Infantry for duty with that regiment.
Capt. Paul Shillock, Asst. Surgeon, so much of the order as directs him to proceed to Key West, Fla., and report to the commanding officer Twenty-fifth Infantry, is amended so as to direct him to proceed to Chickamauga National Park and report to the commanding officer of that regiment for duty with the first detachment thereof that may proceed to take station at Ft. Jefferson, Fla.

ADDRESSES.

ADDRESS AT THE CLOSING EXERCISES OF THE ARMY MEDICAL SCHOOL, WASH- INGTON, D. C., APRIL 1, 1898.

BY P. S. CONNER, M.D.
CINCINNATI, OHIO.

Gentlemen of the Army Medical School: With the appointment in 1789 of a surgeon and four surgeon's mates to the regiment of infantry and battalion of artillery begins the history of the Medical Department of the United States Army. For more than a hundred years it has had the respect of the country and the profession; especially since 1832, when the rule was established that entrance to it should be through examination, severe yet fair, having regard to professional and general education and to physical and mental aptitude for service, a rule that so far as I know has never but once been set aside, except with reference to Medical Inspectors during the rebellion. What has this picked body of medical men done to entitle it to such respect, and what in deeds and words has it added to the stock of professional knowledge upon which all the world is drawing? Of its special work, its care of the soldier, it does not become me to speak, a long-time civil practitioner, who yet counts it one of the joys of his life that he was for a while in the service, and when he thinks of the Medical Staff repeats to himself with pride, *pars minima fui*. Upon a medical officer of the Army, or at least an officer of the Army must devolve the duty of showing how in peace and in war, in camp and on the march, in lowland and in highland, in city and in country, on the desert or on the sea, in many places and under varying circumstances, the members of the Corps have ever had regard to the welfare of the soldier, have protected him from outside and oncoming physical ills, have professionally cared for him when sick or wounded, and by proper feeding, clothing and housing have secured to him such health and strength as have made him in the highest possible degree the defender of his country and the conservator of the public peace.

But of what has been done for the community at large, for Medicine, its art and its science, I may speak, and that all the more freely, because of personal feelings. Almost simultaneously with the organization of the Department began the march of that army of occupation that has swept over and taken possession of the interior valley of the Mississippi, the region of the great plains, the mountain ranges of the continental backbone, the seeming desert lands between the Rockies and the Sierra Nevada, the fertile lands of the western slope, all that imperial area that stretches from the Lakes to the Gulf, from the Alleghanies to the Pacific. In the front line of the on-going thousands of pioneer settlers, and generally well in advance of it, went the Army, establishing here and there little

permanent posts, centers from which offensive movements could be made, rallying points where protection could be had, the beginning of not a few of our crowded cities in the midst of great States full of people and abounding in wealth. To the medical officers at these various forts for longer or for shorter time the growing civil populations had to look for care in sickness and when injured and in many a place that today boasts, and with reason, of the eminence of its physicians and the skill of its surgeons the early chapter of professional history is the record of the deeds and the influence of the surgeons of the Army. From one know many. Dr. Richard Allison, who on Sept. 29, 1789, was commissioned surgeon of the infantry regiment, was at once ordered to the just organized post of Fort Washington, which for "seven years became the headquarters of all the armies that fought against the Indians under Harmer in 1790, St. Clair in 1791, and Wayne in 1794." He was Cincinnati's first physician; and Drake, who knew him well, says of him: "Whenever stationed here (i.e. in Cincinnati) he gave such assistance to the people of the village as made him a general favorite." Resigning in 1798 he spent the rest of his life in or near the city and was the first physician who died within its limits. "Though not profound in science, he was sagacious, unassuming, amiable and kind." (Drake.) Besides Allison, there lived and practiced at Fort Washington and in "the young village" during the first years, Carmichael, Phillips, Sellman, Elliot and Strong, of whom Sellman, after his resignation in 1794, remained in practice until his death in 1827, and Elliot, after the disbanding of his regiment in 1802, settled in Dayton, Ohio, and died there seven years later.

At quite an early day this outside practice must have been viewed with little favor by the authorities of the War Department, perhaps because it may have been found to conflict with the proper discharge of official duties, perhaps because sufficiently interfering with local physicians to give rise to political complications. Whatever the reasons therefore, the Regulations for the Medical Department established in 1814 directed that "No Surgeon of the Army shall be engaged in private practice," and like prohibition had place in the Regulations of 1821. On this subject, Surgeon Harvey Brown ("The Medical Department of the United States Army from 1775 to 1873") writes: "Probably the retention in the foregoing regulations (those of 1821), of the paragraph forbidding officers of the corps to engage in private practice will excite some surprise. It certainly did at the time, for although it was originally incorporated with the regulations of 1814 it had never been enforced; in fact the position of the frontier posts and the comparative scarcity of physicians fifty years ago rendered it often an act of humanity for them to afford professional assistance to citizens living in the vicinity of the garrison." After the distribution of these regulations,

Post-Surgeon McMahon wrote to Dr. Lovell on the subject and the Surgeon-General replied that "the regulation forbidding army surgeons to engage in private practice was intended to prevent neglect of duty by entering extremely into it, as well as an improper application of public property, which often occurred. There would be no objection to this practice provided the officer desiring it would make an application to the Secretary of War, through the Surgeon-General, setting forth clearly the circumstances, in which case especial authority would be granted." As late as 1845 the physicians of Sackett's Harbor, N. Y., protested to the War Department against the surgeon at Madison Barracks attending patients in that village. The protest was not very favorably received, if we are to judge from the letter written by the Acting Surgeon-General.

But not alone for professional aid is a debt due by many of the communities in the Middle, Southern and Western States. Scattered here and there in medical and scientific journals, and especially gathered together in the two volumes of the "Medical Statistics" issued in 1840 and 1856, and in the reports of the various departments and bureaus in Washington, is much information respecting topography, climatology, ethnology, geology, zoology, botany, each and all of these departments of what for the time being may be called local science; information gathered up and communicated by the medical officers of the army, greatly increasing the amount and accuracy of the general knowledge of the sections and districts over which the army had traveled or in which for longer or shorter time it had rested.

The debt of the physicians of the country is yet greater, for while owing as much as citizens at large for what has been given along the lines indicated, they have been the recipients of not a few technical, professional, scientific and practical contributions each of value, some of value hardly to be worthily estimated. Take from our present knowledge of malaria, of cholera, of yellow fever, of typhoid fever, of mountain fever, of dysentery, of diarrhea, the published results of the observations, experiments and studies of Sternberg, of Porter, of Pitcher, of Woodward, of Smart, of Tripler, of Coolidge, of Hammond, of Bartholow, of McClellan, not to mention many others, and the resulting gap would be wide and deep. It will belong before in any discussion of the scientific place and practical value of hygiene and hygienic studies due notice will not be taken of the labors of Billings, of Hammond and of Smart, or before any student of the history of hospitals or the methods of their construction with associated merits and demerits overlooks the published writings and the special work of Billings and of Cowles. The literature of surgery is full of the outcome of the genius and the skill of the officers of your corps. It is with no little astonishment that I read of some of the work done in pre-anesthetic and pre-aseptic days, with no skilled assistants and with most limited appliances; as Pitcher's successfully suturing a completely divided ileum and of Beaumont's conducting to a satisfactory termination a case of lacerated and contused wound in which a charge of duck shot blew off "integuments and muscles of the size of a man's hand," fractured and carried away the "anterior half of the sixth rib," fractured the fifth, lacerated "the lower portion of the left lobe of the lung and the diaphragm," and perforated the stomach.

Passing by for the present the various reports made

to the Surgeon-General and published by the War Department, let us notice some of the work done, the results of which have been given to the world in journals, monographs or more formal books. I have had neither time nor opportunity of so examining the periodical literature of our country as to learn how many medical officers of the army have been contributors, to what extent and upon what subjects, a task that would have been a pleasant one had it been possible for me to undertake it; but I have found that to the *American Journal of the Medical Sciences* during its sixty years' life as a quarterly, nearly fifty of the corps contributed articles (some one, some many) on very varied topics, medical, surgical, therapeutical, obstetrical even, and if to these were to be added those who had once been in the corps but having resigned were at the time of writing in civil practice, the number would be a much larger one. In the Transactions of several of the medical congresses, international, national and special, that have been held in the last twenty-five years can be found able papers by officers of the Corps. At Philadelphia in 1876 Woodward delivered one of the general addresses, as did Billings in London in 1881; at the "Pan-American" in this city Surgeon-General Sternberg was chairman of the Section on Military Medicine and at Denver in June he will preside over the meeting of the AMERICAN MEDICAL ASSOCIATION.

To the various systems and handbooks that have appeared lately a few of the staff have been contributors. Your distinguished chief, who has received many honors at home and abroad and deserved them all, who has been especially concerned with the causes of things and has aided much in their discovery, who after a long and broad training in the school of practical work turned to the experimental side of medicine and has made himself *facile princeps* among American bacteriologists, he, with a number of his colleagues (Adair, Bache, Greenleaf, Huntington, Pilcher, Smart, Smith, Taylor, Woodhull and Woodruff), contributed to the "Reference Hand-book." Billings, scholar, writer, organizer, man of affairs, more widely known perhaps and certainly academically more honored than any other medical man our country has ever had, was one of the writers for Pepper's "System of Medicine" (on hygiene) and for Dennis' "System of Surgery" (on the history of surgery); and to the latter your professor of surgery (Forwood) contributed a masterly article on "Military Surgery." For Ashhurst's International Encyclopedia Clements wrote on the "Field Duties of Military Surgeons," and Bill on "Saber, Bayonet and Arrow Wounds;" the latter a clear, interesting paper, the last perhaps that will ever be written upon these subjects, almost certainly so upon that of arrow wounds.

The books that have been written on professional subjects by medical officers of the Army, though few in number, have been of decided value. As early as 1813 Surgeon-General Tilton published his "Economic Observations on Military Hospitals and the Prevention and Cure of Diseases Incident to our Army," and three years later was issued Dr. Mann's "Medical Sketches of the Campaigns of the War of 1812," together with a dissertation on dysentery and on broncho-pneumonia, both books of much interest not only to army surgeons but to those of the profession at large who may wish to know what was seen and thought and done in the earlier years of American Medicine. In 1833 appeared what may properly be regarded as

the most valuable medical contribution from the Army prior to the publication of the great Medical and Surgical History of the War of the Rebellion, Dr. Beaumont's "Experiments and Observations on the Gastric Juice and the Physiology of Digestion." The case already referred to of wound of the anterior left chest and stomach under Beaumont's care was practically healed in two years' time, and a year later (May, 1825) the Doctor commenced his first series of "Gastric Experiments" at Fort Mackinac. "In the month of June following," he writes, "I was ordered to Fort Niagara, N. Y., where, taking the man with me, I continued my experiments until August. About this time (August, 1825) I took St. Martin with me to Burlington, Vt., and from thence to Plattsburg, N. Y. From the latter place he returned to Canada, his native place, without obtaining my consent." Four years later through the aid of the agents of the American Fur Company "after considerable difficulty and at great expense" the Doctor had the man with his wife and two children brought to him at Fort Crawford, at the mouth of the Wisconsin River, "a distance of nearly two thousand miles." From now on for about two years there was carried on uninterruptedly another series of experiments on the stomach and gastric fluids. Then followed an interval of about eighteen months during which the man was at his Canadian home, after which from November, 1832, to March, 1833, the experiments were carried on again at Plattsburg and in Washington, the man being "constantly subjected to a continued series of experiments on the interior of the stomach; allowing to be introduced or taken out at the aperture different kinds of food, drinks, elastic catheters, thermometer tubes, gastric juice, chyme, etc., almost daily and sometimes hourly." The opportunity was an unique one, and Dr. Beaumont appreciating the situation had the genius to inaugurate and the patience to execute a series of experiments which, rendering him famous, was of immense importance in determining the physiology of digestion. All of his conclusions are not today accepted, but everywhere and by everyone his facts are and his labors are acknowledged and appreciated.

Years afterward the profession received from the Army another contribution of much value on physiologic subjects, the "Physiological Memoirs" of Surgeon-General Hammond, made up of various papers written during his term of service as assistant surgeon, one of them a prize essay of the AMERICAN MEDICAL ASSOCIATION. At about the same time this author, who has written so much, so well and on so many different topics, gave to the Army and the country a treatise on "Military Hygiene." The medical staff carried off another of the AMERICAN MEDICAL ASSOCIATION prizes when in 1876 Assistant Surgeon Culbertson (retired) submitted an essay on "Excisions," a volume in size, the preparation of which necessitated enormous labor, which will long remain as one of a few books that must be consulted by anyone working up the subject of operations done upon the six larger joints. From time to time we have had from the pen of Dr. Billings volumes upon hospitals, upon hygienic subjects, upon ventilation and heating, upon vital statistics, and a medical dictionary, and, as is true of all that the Doctor has written, they prove that he has ever heeded his own advice, "have something to say and say it." To Surgeon-General Sternberg students and practitioners are greatly indebted for a

treatise on malaria, a translation of Magnin on "Bacteria," which came so opportunely, and his own elaborate "Manual of Bacteriology" and associated "Text-book," at home and abroad accepted as authoritative and worthy of both subject and author.

Of all the literary work done by the Medical Staff of the Army far and away the most important has been that connected with the preparation of the Medical and Surgical History of the War of the Rebellion and of the Index Catalogue. Increasing knowledge, changing views of nature and cause, variation of type, fickleness of fashion which has no little influence upon professional opinions, one and all bring it to pass that few books have other than an ephemeral existence. As the elder Gross once said to me "How seldom it is that a man's labors outlast him." But once in awhile there appear the writings of a Hippocrates, a Galen, a Vesalius, a Paré, a Sydenham, a Hunter, a Bichat, a Virchow, and they become as immortal as Medicine itself. Among the never dying will be the two great works just mentioned. The accumulation of immense material, the having at hand clerical aid in quantity and quality equal to the requirements, the countenance of a willing Department and the financial backing of a great nation permitted of that being done which had never been done before, will probably never be done again in like degree and could not have been done under any less favorable conditions. The opportunity was there and the Medical Staff of the Army had the cultivation, the judgment, the persistence, the literary skill that was required. There was most fortunate conjunction of the time, the place and the men. Had they done nothing else the preparation of the Medical and Surgical History and of the Index Catalogue would have perpetuated the names of Otis, of Woodward, of Smart, of Huntington, of Billings; and with them should be mentioned their associates of the Corps whose less prominent work was yet of no little value. At once a treasure house and a mine, the Medical and Surgical History reports facts, presents statistics, discusses theories, compares opinions, weighs treatment, and all the while bears testimony to the fidelity, the skill, and the devotion of that army of medical officers, regular and volunteer, that was fighting disease and injury during the long years of that terrible strife. In the midst of arms Law is silent, Medicine never. From camp and field and hospital she has always spoken and she never else has spoken so loud, so long, so authoritatively as in our day and on our soil. The epitome of her teaching is this History. Though the advances of the last thirty years in knowledge of the causes, the means of production, the most favorable methods of treatment of the diseased conditions prevalent in armies reader even now much that was learned in the ten years before of comparatively little practical value; though alterations in armament will cause much change in number, character and gravity of wounds and therefore in the care of them, still these six ponderous volumes will long have to students and practitioners, military and civil, much more than a mere historical value, great as that may be.

Of much more present practical value to the profession at large is the Index Catalogue which with the supplementary Index Medicus has for nearly twenty years been making us familiar with what has been and is being written on each and every medical subject. In most unusual degree it has been filling a long-felt want, and both at home and

abroad has been furnishing students and writers with what was heretofore unattainable. The magnificent library around about us, in so great a degree the outcome of the labors of Dr. Billings, has supplied the material for the work. The high scholarship and peculiar fitness for editorial supervision that have long characterized Dr. Billings and his co-laborer Dr. Fletcher have guaranteed fulness and accuracy of selection and classification; the abundance of clerical aid has secured extraordinary regularity and rapidity of appearance of the successive volumes. A first series completed, a second is bringing the catalogue up to date; and the declaration may safely be made that the Medical Department of the United States Army has accomplished the most gigantic, important and useful medical task known to history. Over and above this literary work it has accumulated stored and scientifically arranged a museum that so far as relates to the diseases and injuries of soldiers is unapproached and in all probability unapproachable.

Keeping in mind the things done, the services rendered, the influence exerted by the officers of the Medical Staff through all these many years, who can rightfully refuse to the Corps full meed of respect, full measure of honor? True, more perhaps might have been accomplished; not a few bright minds have suffered eclipse; there has been much loitering on the way; but our Country and our profession are and ought to be proud of their most carefully selected body of medical men. Many of its members have gone out into civil life, carrying with them those principles of honor and integrity and devotion to duty that are the very life and soul of an Army Officer. You may well take pride in the labors and the successes of such general practitioners as Heustis and Pitcher and Porter, of such surgeons as Van Buren and Weir and Gouley, of such gynecologists as Homans and Lee, of such oculists as Thomson and Norris and Fryer, of such laryngologist as Asch, such alienist as Cowles, such anatomists as Isaacs and Allen, such chemists and scientists as Torrey and Bache, such zoologists as Coues and Schufeldt. The names of at least twenty-five of the medical teachers in almost as many schools have at one time or another been borne upon your rolls, and among them are those of Bartholow and Dunster and Glison and Pooley.

Thanking your Dean and the Surgeon-General for the honor that they have done me, it is with much pleasure, gentlemen of the Army Medical School, that I congratulate you on the completion of your academic labors and wish you all success in the life that is before you. In having the opportunities for special training here afforded you have been far more fortunate than were your elders. Of all the good work that Surgeon-General Sternberg has done none will prove to have been better than the establishing of this School, and you may be sure that in every effort to increase your scientific knowledge and to add to the sum total of the world's information on matters medical you will have the sympathy and aid of your Chief. Personal experience long ago taught him how hard it is to make bricks without straw, to follow out in army life careful continued accurate investigations without the support of—more, in the face of the opposition of—the higher officers of the Department. With you, under the present order of things, it will certainly be, the more labor the more favor. Will you pardon me if I suggest to you that while you are military surgeons you are medical men and Medicine

is greater than any of her departments. As far as may be possible, put yourselves in close touch with the general and local profession, and as you may freely receive freely give. The long time isolation of the surgeons of the Army has come to an end with the conditions that necessitated the establishment and maintenance of many and widely separated posts. As your duties call you to the vicinity of cities that are, in greater or less measure, medical as well as commercial and political centers, take your places as members of the greater and higher Medical Corps that embraces all the good men and true who are advancing Medicine and benefiting mankind. Again congratulating you, I bid you God speed.

THE RELATION OF THE MEDICAL AND LEGAL DEPARTMENTS OF RAILWAYS.

President's Address Delivered at the Annual Meeting of the American Academy of Railway Surgeons, at Chicago, Ill., Oct. 6-8, 1897.

BY L. E. LEMEN, M.D.

DIVISION SURGEON UNION PACIFIC SYSTEM,
DENVER, COLO.

CONNECTION BETWEEN LAW AND MEDICINE.

Law and medicine, like "knowledge and wisdom," are "far from being one," but here Cowper's distinction ceases to apply, for the connection between the two professions is close and intimate, and each new discovery in this age of rapid, scientific progress unites more closely these great branches of learning. Medical jurisprudence has widened far beyond testamentary capacity, commissions in lunacy and expectation of life. The toxicologist and the chemist are quite commonly assistants of both commonwealth and accused in capital trials; the surgeon, the bacteriologist and the biologist are hand in hand with attorney and counsellor in civil and criminal causes. Where the *Green Bag* or the *London Lancet* was once filed alone, the *Medico-Legal Journal* now shares shelf space and attention, and the journals of both professions devote much printed space to medical jurisprudence and medico-legal surgery.

The Medico-Legal Society, from an insignificant local association, has grown to be an international organization; strong numerically, stronger intellectually, strongest in original research and investigation; throwing light upon problems which have heretofore puzzled alike the disciples of Blackstone and of Æsculapius, including in their numerous courses of study every subject of common interest, from psychics and hypnotism to compulsory vaccination; from toxicology to our own branch of railway surgery.

POPULAR HOSTILITY TO RAILROADS AND THEIR SURGEONS.

It is popular and profitable to criticise the grinding railroad monopolist in print and on the platform; it is politic in a court room to sneer at the salaried surgeon who has given his best and most conscientious professional services, often under unfavorable and distressing conditions as a "corporation tool and hireling" whose testimony, "well, gentlemen of the jury, you know what expert testimony is worth, especially when the expert has a life position with the corporation. I leave it to your own common sense." In the determined effort to dominate the minds of twelve men, sometimes unintelligent, often uninformed, always

uncertain, courtroom proceedings in railroad cases too frequently degenerate into oratorical appeals, which utterly disregard the underlying, unchanging principle of justice, to be applied without fear or favor to individuals as well as to corporations.

HUMANE PROVISIONS MADE BY CORPORATIONS.

Corporations, like individuals, though born in sin, are not totally depraved. A critical public may attribute them to policy and self-interest, nevertheless the fact remains that the legally and proverbially soulless railway corporations make more and better provisions for accident and emergency cases than individual employers and partnerships engaged in business equally hazardous. The emergency case with bandages, etc., in each engine, the stretcher in every station (Pa. R.R.), the ambulance in large cities, the hospital owned, equipped and operated by the company (U.P. R'y.), or the hospital to which the company makes an annual donation in consideration of care for injured employes, accident and emergency cases (Pa. R.R.), the salaried surgeons at central points, and the rural practitioners whose infrequent services are compensated by a regular "annual" (Pa. R.R., Reading R.R.), all are active agents for the alleviation of the ills of humanity, though the public deny their principal the credit of putting them in action for humanity's sake.

RELIEF DEPARTMENT, ETC.

Is it solely for the benefit of the company that relief departments are organized with sick and death benefits for employes, whether the illness or death results from accident or from natural causes? Is it solely for the company's benefit that surgical attendance is furnished during disability from accident in the company's service; that trusses, artificial limbs, etc., are supplied for injured employes, that pensions are planned for old age?

Certainly the relief department contract bars the beneficiary from bringing suit against the company. But for the numerous accidents caused by his own negligence or the negligence of his co-employes, the employe had no legal right of action. Yet in both these instances the relief department pays the monthly disablement benefits for a year or more (Pa. R.R., Reading R.R.)

NECESSITY FOR RAILWAY PRACTITIONER AS A SPECIALIST.

To reiterate a truism, railroading is a hazardous occupation. Though the greatest possible care be observed, though the latest improvements be used, some accidents are inevitable, some collisions are sure to occur; trainmen are as surely predisposed to certain diseases as glass cutters or workers in emery. Higher rates of speed, lengthening miles of track, increasing forces of train workers strengthen and render imperative the necessity for an intelligent body of medical men who make railroad practice a specialty. The opinions of a fickle and often wholly unreasonable public have small place and smaller influence in a profession which listens to the first cry of the living and the last moan of the dying, and hears through all its years of active service only the wails, the woes and the weaknesses of humanity. Medical men have no time to reply to healthy critics. The sick must be healed, the helpless must be strengthened, the mangled must be relieved, and whether he be oculist or neurologist, gynecologist or railway surgeon, the man who gives his best services to the sick and dying is accountable to his own conscience, and to that only, whether his compensation

be the check of a corporation or an individual, gold from a bank or silver from a stocking, or whether such compensation never comes at all.

RAILWAY SURGEON HONEST RATHER THAN INTERESTED WITNESS.

No individual seeking to perpetrate a fraud upon a railroad company through an eloquent appeal to the sympathies and prejudices of a jury, and the complaisant testimony of irresponsible physicians with an eye single to the enlargement of their private practice, has a right to expect any evidence from a railway physician but the truth. And no general manager, no division superintendent, no relief department, no board of directors, no corporation, seeking to perpetrate a fraud against an individual through pressure upon salaried employes has a right, because of salary paid for medical services, to any testimony from a railway surgeon save "the whole truth and nothing but the truth."

ANOMALOUS POSITION OF RAILWAY SURGEON AS A WITNESS. THREE-FOLD RELATION.

In hospital or home, in collision or office examination, the railway surgeon is as other physicians, but as a witness in actions against the railroad by persons who claim to have been injured through the company's negligence, his position is strikingly anomalous:

1. He is the employe of the defendant railroad in whose behalf he is called to testify.

2. He was the physician of the plaintiff against whom or by whom he is called to testify at the period most in controversy. Further, this professional relation was many times initiated under circumstances which gave the plaintiff no option save death or acceptance of the railway surgeon's services, and sometimes a merciful insensibility deprived him of any option whatsoever.

3. He is called by the defendant company as an expert witness in their behalf.

The difficulties of this three-fold position are self-evident, the responsibilities definitely aligned, the duties not so clearly defined.

Having survived the omniscience of youth, the writer submitted the following hypothetical question to ten physicians and ten attorneys, equally divided in numbers as to affiliations with or against corporations.

What do you, as a physician (or attorney), think a railroad company has the right to expect from an attending physician in their employ, as witness in an action brought against the railroad for injuries alleged to have been received through the company's negligence?

Twenty unqualified declarations for the "whole truth and nothing but the truth," are followed by varying comments on statutory regulations concerning medical witnesses, and by criticisms of railway influence on supreme courts, and of juries for unjust verdicts against companies in obedience to popular clamor.

AS MEDICAL EXAMINER.

There can be no question that if the railway physician comes in only as medical expert for the company, having examined the plaintiff in that capacity, he is at liberty to tell anything he learns from such examination.

AS ATTENDING PHYSICIAN. LEGAL BARRIERS.

If he be called by the company as the surgeon who attended the plaintiff at the time of the accident or disablement, in many States his lips are sealed by ex-

press statutory enactment forbidding physicians to divulge facts learned in the course of professional service. Others effect the same object by not permitting physicians to divulge facts which would be a bar to the patient in a subsequent civil action. (Penn. etc.)

On the other hand, membership in a relief department commonly includes contractual renunciation of the right of action; hence, for a large body of employes, the surgeon's testimony is not needed. The written law of at least one (Col. State Statutes) State, however, expressly prohibits contracts (conflicting interests) between corporations and their employes, which relieves the company from liability for accidents caused by the negligence of the corporation or its servants, and pronounces such contracts null and void. Here the railway surgeon comes in as the necessary and most responsible witness on both sides, as he must needs be, in many cases where the plaintiff is an injured passenger.

PROFESSIONAL DUTY.

His duty to his profession requires that he state the facts so simply that the non-professional juror may understand; so accurately that his brother physicians may recognize their physiologic correctness, gather helpful ideas from novel and peculiar cases, and hints for future testimony.

PROFESSION AND DUTY THERETO FIRST, RAILWAY EMPLOYMENT SECONDARY AND INCIDENTAL.

The matter of salary has no bearing on the subject. From his student days till his hands are stilled, the surgeon cheerfully gives the same skill to the poor that the rich receive for large reward. The great and beneficent discovery of his life is not patented like an air brake or a car coupler, but freely given to humanity through printed and professional channels. He is first and always a physician; the railway employment is only an incident; if it terminated he would still be physician and surgeon. It follows that the duty to himself, his profession and his patient, is his highest duty, and no railroad company or its attorney has any right by suggestion, intimidation, or, in any manner whatsoever to seek the suppression of the facts in the case as the attending surgeon believes them to be.

"Keep your eyes and ears open and your mouth shut," is an excellent rule in the ordinary line of duty, for hospitals, and in the confusion of accidents and emergencies, but to expect a physician to keep silent when duty demands and the law lays upon him an obligation to speak, is to suggest indirectly that he is the unhappy possessor of a strabismic or an astigmatic conscience.

RELEASE BY COMPANY.

Where the facts and circumstances are against the company's interest it is quite as much the attending surgeon's legal and moral duty to disclose them as where an unscrupulous plaintiff seeks by fictitious ailments and symptoms to procure an award against the company to which he is in no way entitled. If his view of "the whole truth and nothing but the truth" conflicts with the company's interest, the attending railway surgeon should be altogether released and relieved from acting as a witness in their behalf. The novel spectacle of a railway surgeon testifying against his employing company would certainly be unprofitable to the corporation in the first instance; but in the long run, the self-evident facts that the surgeon employed maintained his profes-

sional and individual honor, and that the company sought only truth and justice in the case, would prove of financial advantage to the corporation, lessen the number of suits brought, decrease the amount of damages awarded, and overcome the existing legal prejudice against railroads and their employes.

PREJUDICE AGAINST EXPERT TESTIMONY.

Physicians have sold themselves in times past to tricky claimants; physicians have been bought in by-gone days by conniving corporations, with the legitimate result that expert testimony, however honest, however skilful, however conservative, is today at a discount with both court and jury. The expert witness is a subject of raillery; his testimony accounted of so little value that it is passed over in silence, or only commented upon in a general way. When the medical expert is a railway surgeon the jury's prejudice is increased fourfold. The cross-examiner's gibes and thrusts are received with ill-concealed approval. In a recent case the plaintiff's attorney in his Buzfuzian appeal to the "arbiters of the destiny of a freeman," vehemently inquired, "gentlemen of the jury, are your opinions to be formed and shaped by that brass-buttoned receptacle of railroad rations?" And the jury promptly negatived the interrogation by an award of \$10,000 to the plaintiff. Extreme! Not so extreme as a late Pennsylvania case which gave a plaintiff \$30,000 for an injury which was a physiologic impossibility under the facts stated. (Webster vs. Electric Traction Co., Philadelphia, Pa., 1896.)

ON THE STAND. PHYSICIAN'S BEST METHOD TO DISPEL PREJUDICE.

The medical expert and the railway surgeon are admittedly necessary witnesses in suits brought against the company by persons injured. The prejudice of courts and juries against expert testimony, and the prejudice of juries against railroads and persons in their employ are matters of common knowledge. Therefore, it behooves the railroad physician to consider how he may most effectively destroy the barriers which ignorance, prejudice, and the misconduct of others have builded in his way as a witness.

EXAMINATION.

He is familiar with the facts in controversy, he knows the medical principles applicable to them. Consultation with the company's solicitor has covered the interrogatories of the direct examination. His honest, conscientious statement of the case is strongly in favor of the railroad. Then the cross-examiner takes him, and the real battle commences with an expert inquisitor, whose sworn duty to his client requires that he shall exert every effort to weaken the force and effect of the surgeon's testimony. In the hands of a wily antagonist who seeks (cross-examination) to annoy, embarrass, confuse, irritate, anger, disconcert and ridicule him, it is so much easier to say what a witness should not do than to make affirmative suggestions, that I have put my own few thoughts mainly in negative form.

SUGGESTIONS AS TO TESTIMONY.

1. Use no technical language, unless absolutely unavoidable. The juror is a plain man, ignorant of medical terms. The speech of the common people is his own tongue, and the man who makes him understand, wins the verdict. The sternum and the patella are unknown quantities to him; the breast-bone and the knee-pan are useful members, the value of which to a wage-earner he can estimate with considerable

accuracy. He has two eyes as well as two ears. A bone, a lead pencil, and a twisted piece of paper sometimes double the chance of success. Object teaching is the natural method; demonstrate the facts where practicable.

2. Avoid controversies with the cross-examiner. The war is unprofitable because unequal; he can strike when the surgeon is down; his last turn with court and jury comes when the medical man is no longer an active participant in the case.

3. Keep sweet. He who loses his temper loses his cause. Questions are frequently asked for the express purpose of irritating the surgeon; an exhibition of anger is the very result desired, and the first ruffling of composure is welcomed as a successful assault on the enemy's works.

4. Talk slowly; take time to answer questions fully. Minds untrained in medical lore can not follow and comprehend professional explanations at the same rate of speed as assistants at a clinic.

One of the most common methods of perplexing a witness and neutralizing the effect of his testimony is to fire volleys of rapid questions at him. Half finished, hastily given answers create erroneous and contradictory impressions; hence the necessity for deliberation throughout expert testimony, and an utter disregard of attempts to undo the surgeon through undue haste.

5. Answer the question asked. He who volunteers information or explanation digs a pit into which the cross-examiner shall shortly but surely tumble him. In the infrequent instances where "yes" and "no" will not suffice as answers, an explanation of the cross-examiner's ingenious verbal trap will be developed by questions of opposing counsel on re-direct examination, or will be permitted upon request to the court for opportunity to make the matter clear.

6. Answer briefly. The best approved judicial proceedings are in accord with the petitions of those Indian Territory negroes who habitually besought the Judge of all hearts to grant them "long prayers and short answers." The plaintiff in his complaint or declaration "ever prays," and the defendant in his answer "will ever pray," at considerable length and with much technical repetition, but that surgeon most helps his cause who in his testimony gives short answers and shuns technicalities.

7. Say, "I do not know." The surgeon who knows everything is clay in the hands of the cross-examiner, and malformed or formless clay in the verdict of the jurymen.

8. Do not discount the medical information possessed by the cross-examiner. Thousands of lawyers beside Lord Eldon have studied medicine before reading law. Lacking a medical education, the lawyer prepares his case by repeated consultations with leading physicians, by reading articles in medical journals and by careful examination of the accredited medical authorities.

As was recently said by a distinguished New York attorney in addressing the graduating class of a great medical school, "The medical profession differs from the legal in the fact that the physician is not expected to know law, but the lawyer must have a familiar and comprehensive knowledge of medicine."

JOINT AIMS AND ACHIEVEMENTS OF MEDICINE AND LAW.

Personally the doctor may never need the lawyer's

services, though the attorney is sure to require the physician's ministrations; but professionally the advocate who fights against oppression is the blood comrade of the physician who battles against death. Together they have warred for the rights of the poor, the helpless and the despised; together they have defied kings and corporations. When, in the darkness of the middle ages, all other good seemed lost, the doctor and the barrister stood alone as mouthpieces and interpreters of the common people—solitary champions of liberty and justice, unconquered and unterrified by kings. In our own day, through their joint efforts, boards of health have been organized, State and Government inspection of water and food products introduced, reformatories and insane asylums reconstructed, prison conditions ameliorated and upheaved, and many other great reforms instituted.

HIGH MORAL STANDARD DEMANDED OF PHYSICIAN AND ATTORNEY.

There can be no human liberty without law; there can be no healthy human liberty without medicine; the tyranny of rulers and the tyranny of disease alike reduce men to slavery. "*Noblesse oblige*," said the old French king, and he who breaks these shackles from humanity must regard neither men nor money, neither position nor power. Leprosy and smallpox are less to be dreaded than the moral contagion of dishonor. Whether in clinic or court room, whether beside the sickbed or before the bar, temporizing, policy, the "necessity" which Pitt called "the argument of tyrants" and "the creed of slaves," are only weights he has laid aside. His rule of life is the Supreme Law enunciated by the Great Healer: "Ye shall know the truth, and the truth shall make you free;" and his earthly ambitions are summed up in Wolsey's counsel to Cromwell:

"Be just and fear not.

Let all the ends thou aims't at be thy country's,
Thy God's, and truth's, then if thou fall'st, O Cromwell,
Thou fall'st a blessed martyr."

—Shakespeare, *Henry VIII*; Act III: Sc. 2.

THE SURGERY OF THE BRAIN.

Address delivered before the Austin Flint Medical Society, Clear Lake, Ia., July 20, 1897.

BY ALBERT I. BOUFFLEUR, B.S., M.D.,

Professor of Anatomy and Clinical Surgery, Northwestern University
Woman's Medical School; Demonstrator of Operative Surgery, Rush Medical College; Attending Surgeon
Cook County Hospital, etc.

CHICAGO, ILL.

The surgery of the brain and its membranes has within the last two or three years received more merited attention than during the preceding decade, when the great surgical world spent a large portion of its energy on that important class of diseases which are found in the abdomen and which are now so generally subjected to surgical treatment.

All subjects which directly affect the life of an individual are of special interest to the conscientious physician and certainly there is no class of diseases which are more obscure in their symptomatology, more erratic in their course, more discouraging in their treatment or more uniformly fatal, when managed expectantly, than the lesions of the brain, which are now subjected to surgical treatment.

The peculiar anatomic conditions in which the organ under consideration is placed renders the opportunity for careful observation of very rare occurrence, while the location of the vital centers in the lower brain precludes all thorough and systematic investigation upon man. It is only by clinical observation then, that even a fairly comprehensive knowledge of the location of the foci of physiologic action and of diseased processes has been adduced. The pathologists have discovered inflammatory, suppurative and adventitious processes in the brain for many years, and they have also been able to classify the various lesions which are found therein, and even to finally differentiate between types and degrees thereof, but until these lesions could be clinically located with a fair degree of certainty, the local treatment was of necessity purely empirical.

Experimental research on animals and clinical observation with postmortem findings in man, led to the discovery of motor centers and later of centers for special sense, and more recently closer studies have outlined the cortical centers for different varieties and degrees of physiologic manifestations. With the location of the physiologic centers came the possibility of the clinical diagnosis and location of disease processes. As these processes were subjected to surgical treatment in other parts of the body with a large degree of success, it was but natural that this field was considered an inviting, though admittedly difficult one, for the exercise of the surgeon's skill and dexterity.

Operations upon the brain were so uniformly fatal in pre-antiseptic days that the surgery of the brain was, by common consent, limited to emergency work. The protection afforded by antiseptics and asepsis has rendered the cranial cavity safely approachable, while the various improvements in the methods of trephining and means for its execution have rendered much of the cranial contents readily accessible.

Successful cerebral surgery depends upon three essential elements, viz., the diagnosis of the character of the disease, its anatomic location and the proper operative technique. The purpose of this paper is to briefly present the nature and diagnosis of cerebral lesions, to emphasize the importance of cerebral localization and to discuss the advisability of subjecting our patients with cerebral diseases to operations for the relief of their troubles, and if an operation is deemed advisable, how it should be performed to obtain the best results. The diagnosis of most of the conditions which we will consider should be made or confirmed by a neurologist when possible before being surgically treated.

CEREBRAL LOCALIZATION.

In considering this subject it is well to remember that while there are points or small areas of the brain in which the reaction to stimulation is most marked, the area of lesser reaction extends in most instances far over into other areas so that the various centers or areas overlap each other. This fact explains the observation that when a primary anatomic center only is removed the function ascribed to that area may not be wholly paralyzed. It is also recognized that these areas are not confined to any single convolution or even lobe, but may be located in two or more.

The areas which are now generally conceded to be definitely located are the motor-sensory area, the speech area, the visual area, the auditory area and the

area for smell and taste. In addition, later investigation seems to have established the fact that there is a center or centers for muscular sense and to have determined its probable location.

1. The motor-area is located in the convolutions bounding the fissure of Rolando and those adjacent thereto; those of one hemisphere control the movements of the opposite side of the body, while the general arrangement of the centers is in inverse order to the location of the parts controlled; the highest centers being for the leg and foot while the lowest are for the face, etc. As most people are right handed the left side of the brain is best developed and usually marks the location of the special sense areas.

The upper third of the anterior and posterior central convolutions and that joining them controls the actions of the lower extremities; the toes being controlled by the most posterior part and the foot, leg and thigh in the order named from behind forward.

Immediately below in both convolutions for a distance of about one inch are found the areas which control the action of the shoulder, arm, wrist and hand. The former being located above, in the anterior central convolution, while the hand is governed by the area below, in the posterior central convolution.

The lower third of the Rolandic region marks the location of the areas controlling the movements of face, tongue, etc.; the cheeks and eyebrows being governed from the upper and anterior part, the tongue and larynx by the lower and anterior part, while the movements of the mouth and pharynx are controlled by the lower and posterior part.

In the posterior part of the superior frontal convolution the center for the muscles of the trunk is found. (Horsley.)

The posterior part of the middle frontal convolution controls the movements of the head and eyes, the former being located above the latter. Stimulation causes conjugate movement in the opposite direction.

The tactile sensory areas are apparently located in connection with those motor centers found in the posterior central convolution, which will have been recognized as controlling the most intricate and delicate movements of the body, especially those of the toes, fingers and lips. Immediately behind these centers the area for muscular sensation is also supposed to be located.

2. There are four speech areas which are all located on the left side of the cerebrum in right handed persons and on the right side in left handed persons.

The motor speech area is located in the posterior part of the third or inferior frontal convolution and controls the movements concerned in the act of speaking. Destruction of this area causes motor or ataxic aphasia. When it is only partial it may be manifested by an inability to use certain words or properly place certain letters.

The auditory speech area is located in the superior and middle temporal convolutions. Destruction of this area causes a loss of memory of word sounds—word deafness. The patient is unable to recall the names of objects or to understand the language spoken.

The visual speech area is located in the lower parietal region, in the angular gyrus. Its destruction causes loss of the power to read or understand written language—word-blindness.

The location of the area giving us power to write is not definitely determined. There are evidences that it is located in the inferior parietal region but

there have been cases in which destruction of the motor speech area has caused its loss—agraphia.

3. The visual area or sight center is located in the cuneus and cortex of the occipital lobe. As each lobe receives impulses from half of both eyes, a lesion causes hemianopsia, half blindness in both eyes, and the field of blindness is on the opposite side of the lesion, according to Starr, while the Charcot theory is that a lesion of one center causes total blindness of the opposite eye.

4. The auditory area is located in the first or superior and second or middle temporal convolutions. Each ear being connected with both hemispheres, the effect of a unilateral lesion is only partial deafness and is usually not noticed. Bilateral lesions cause total deafness.

5. The area for sensations of smell and taste is located at the tip of the temporal lobe on its inner or under surface. Each lobe is related to the organs of both sides and hence unilateral lesions cause only diminished function.

The location of the psychic center is undecided. Lesions in the frontal lobes have been manifested by little else than mental symptoms, while lesions have been found, postmortem, in the frontal lobes of subjects who have been free from any mental symptoms.

The symptomatology of lesions limited to the basal ganglia is unknown. It is only when the lesion encroaches upon the internal capsule or some radiating or connecting fibers that symptoms are produced.

Lesions in the pons and medulla give rise to irritation or destruction of the cranial nerve centers of the particular region involved.

The cerebellum controls the equilibrium of the body and, therefore, disturbance of its structure is productive of vertigo and staggering.

The works of Ferrier, Horsley, Henschen, Knapp's table in "Strümpell's Practice," Starr and others present the subject more in detail. The diagnostician who contemplates work in this class of diseases should master at least this much of what is known about cerebral localization while the operator should, in addition, be able to locate the areas on the surface of the skull.

The subjects which will briefly claim our attention are trephining for fractures of the skull, intra-cranial hemorrhage, suppuration and tumors, epilepsy, insanity, imbecility, hydrocephalus, removal of Gas-serian ganglion and for pain.

Fractures of the skull.—This subject is considered because it is so frequently attended by evidences of injuries to the brain and its coverings and especially as the expectant treatment thereof is a potent factor in producing those pathologic conditions—hemorrhage, inflammation, abscess, etc.—for which we are called upon to operate subsequently.

Fractures are divided into simple, compound, complicated and depressed. A simple fracture is one unattended by a wound; a compound, one connected with a wound; a complicated, one accompanied by extensive damage to overlying soft parts, or positive injury to the brain or its membranes or to the vessels, or by an infection of the external wound, and a depressed fracture is one in which one fragment is lower than normal and which may or may not be attended by symptoms of cerebral compression. A depressed is a complicated fracture and it may be either simple or compound. Frequently, as in gunshot wounds, we find the three latter divisions associated.

In the absence of a wound, the diagnosis of a fracture is frequently purely conjectural. The nature and direction of the operating force should always be carefully considered. The presence of a well defined swelling with sharp borders due to an exudate or blood clot in the scalp or beneath the periosteum may readily lead one to believe that a depressed fracture is present when, in fact, there is only a circumscribed contusion. Likewise the possibility of congenital and other defects in bone should be considered.

When there is a wound it is, as a rule, easy to determine the condition of the bone although it may be necessary to enlarge the opening to definitely settle the question.

In every case in which there is doubt, the scalp should be sufficiently incised to fully expose the area and admit of a thorough digital and ocular examination. Two preliminary conditions are however requisite: 1, the area should be thoroughly shaved and rendered positively aseptic; 2, the operator should be prepared to perform any operation which the local conditions indicate. There has been much discussion as to the treatment of skull fractures, which has resulted in the formulation of many sets of rules to govern the surgeon. It, however, remains a fact that even those of largest experience are frequently at a loss to know whether to operate or not in a given case. In compound fractures some sort of an operation is always indicated for the excision of bruised and lacerated tissues, the removal of splinters of bone and foreign bodies, the elevation of depressed bone, controlling of hemorrhage, and at least for the proper closure of the wound. In bullet wounds it is generally conceded to be best to leave the missile undisturbed, unless it can be definitely located in a superficial position, the injury to the skull being treated as a compound fracture. The question of drainage must be decided upon the indications of each case. The frequency of the occurrence of traumatic epilepsy and other serious secondary effects, from the old plan of treating fractures of the skull and the fact that when properly performed the operation of trephining is practically without mortality, has led to the establishment of a more advanced plan of treatment in this class of cases. Even in simple fractures the patient should be subjected to operation when there is depression of a fragment or where there are evidences of injury to the intracranial tissues. The full extent of the damage can be determined only by this method, while anything short of it does not permit of adequate treatment where so much is in doubt. If more fractures were thoroughly exposed, more depressions would be detected, and if more depressed fractures were elevated, more blood clots turned out and more spicula of bone removed by trephining, as a primary operation, we would have less epilepsy and other sequelæ which are so frequently traceable to a trauma of the head.

In all cases of fracture of the skull the general treatment should comprise complete physiologic rest, free intestinal and renal elimination and, if necessary, the application of ice to the head.

Intracranial hemorrhage.—In cases when progressive symptoms of compression supervene upon the receipt of a trauma, which are attended by the manifestation of stimulation (irritation) or paralysis of a motor area the diagnosis of hemorrhage is probably justifiable. The gradual development of stupor followed by coma and stertorous breathing, a slow pulse,

a dilated pupil and a rise of temperature to less than 103 degrees makes the symptomatology complete. The differentiation between extra-dural and intra-dural hemorrhage is not sufficiently determined to be of practical value.

Statistics demonstrate the demand for operation in cases where any considerable amount of hemorrhage has probably occurred. Park gives Weisman's reports in which of 147 cases treated expectantly, 131 died, while of 110 treated by operation only 30 proved fatal. Selection of cases would undoubtedly improve these figures. It should be remembered that most hemorrhages occur from the middle meningeal artery and that they are most frequently extra-dural. Where the focal symptoms point to compression of the opposite side the operation should be performed on the side presenting the symptoms.

Intra-cranial suppuration.—This class comprises abscess, suppurative leptomenigitis and thrombophlebitis. Abscess of the brain may be traumatic or non-traumatic. The former variety may develop either soon after a traumatism or years later. Where a wound has been present it is usually indicative of its having been the seat of prolonged suppuration. The non-traumatic variety is usually the result of the extension of an infection from the middle ear, although it may follow an orbital or nasal infection, or may be of metastatic origin. One of the strangest features of cerebral abscess is the great variance of the time of its occurrence. The symptoms of an acute abscess may subside or none may appear, and yet, from some unknown cause, months or years afterward, the symptoms of abscess suddenly develop. Nature has probably succeeded in confining it to a definite region and if that happens to be in an unimportant area of the brain no symptoms may be occasioned thereby, until the protecting wall gives way, when all evidences of an encephalitis are manifested. In making a diagnosis we should always look for a traumatism or a primary suppurating focus, as upon its presence or absence may rest the differentiation from cerebral tumor. In addition to the headache, vomiting, vertigo and symptoms of pressure there may be fever or a subnormal temperature with the probable absence of ocular evidences. In latent abscesses the symptoms are especially obscure and its diagnosis often impossible. Abscess following middle ear disease is of frequent occurrence and deserves much more attention than is usually accorded to it and demands radical treatment. Suppurative otitis may be followed by a leptomenigitis or a septic thrombophlebitis and abscess. If the perforation is upward the lesion will be located in the temporo-sphenoidal region; if backward, in the cerebellar region, while if by an extension of the process through the mastoid veins it will cause a thrombophlebitis of the sigmoid sinus.

The intimate connection of the mastoid veins with the lining of the mastoid cells and the sinus render infection by this route especially likely to occur. The differential diagnosis of the various forms of intra-cranial infection is not always possible since two or more varieties are likely to be associated. Jansen has given this subject special study and states that pyemic fever with repeated chills following a suppurative otitis are indications of sinus thrombosis and if these are accompanied by symptoms of vertigo, restlessness, nausea, rigidity of neck, stupor, etc., operation is demanded. ("Ann. Surg." Vol. xxxiii.) The statistics are very favorable to radical operative treatment.

The treatment of suppuration within the cranium should be upon the same principles as in other regions of the body, with special indications for prompt and radical measures, since the prognosis of expectantly treated intra-cranial suppuration is so uniformly bad. When abscesses can be located they should be exposed and thoroughly disinfected and drained, preferably with gauze packing. If the abscess is in the temporal region, Von Bergman ("Ann. Surgery," Vol. xxiii.) advises operating so as to expose the tympanum and then extending the section as the conditions may indicate. Likewise in sinus thrombosis the sigmoid fossa can be easily reached after exposing the mastoid cells. When thrombosis of the lateral sinus is present the condition of the internal jugular vein should be determined, and if it is thrombosed it should be exposed in the neck, and, after ligation below the location of thrombosis, it should be opened and the sinus and vein thoroughly emptied and disinfected. When the symptoms point to a suppurative leptomenigitis the indication is for thorough drainage, the same as for suppuration in any other serous cavity.

The cranium should be trephined below the superior curved line of the occiput and also above the posterior part of the zygoma (Park). These openings will admit of free irrigation and drainage.

Intra-cranial tumors.—The most common varieties of brain tumors are sarcoma, glioma, tubercle, secondary carcinoma, syphiloma and cysts, in the order named. The symptoms of tumor partake of the same general character as those of all lesions which increase intracranial pressure. Persistent headache, intractable vomiting and optic neuritis, with evidences of focal stimulation or destruction and the absence of a primary suppuration focus, are strongly indicative of cerebral tumor, and should differentiate it from other lesions. Our present knowledge of the symptomatology of tumors is not sufficient to enable us to differentiate except in a general way. The smaller, harder, more circumscribed and less vascular the growth the better the prospects of recovery. They are more frequently located in the base and the cerebellum in children, while in adults the cerebral cortex is fortunately most frequently involved.

About one-third of all brain tumors are located in the basal ganglia and, therefore, situated in a surgically inaccessible region. Nearly one-fourth of the tumors given in "Starr's Tabulation" were located in the cerebellum, whence tumors are excised with the greatest difficulty. One-tenth of the number were multiple in character. The remaining tumors were located in accessible regions. Of these many did not present the necessary focal symptoms, while others were of such size or character as to have precluded their removal. It is then definitely understood that only about 6 per cent. of all brain tumors can be successfully removed by operation. The fact that the diagnosis as to character and location of the lesion is frequently obscure, and that when made it is frequently erroneous, coupled with the inoperability of such a large percentage makes the present field of operative treatment of brain tumors very limited and the prospects for relief in general poor indeed.

Cases of syphilitic and even non-syphilitic growths have been relieved by antisyphilitic treatment, therefore, all cases of tumor of the brain should be subjected to a course of heroic treatment for at least three

months before operation is resorted to. Notwithstanding the limits of the operation and the recognized dangers of the procedure, we must remember that cases which are not relieved by medication gradually grow worse, until life becomes one of mental degeneration and often one of great misery.

In nearly one hundred recent cases collected by Starr the results of the operations have been successful in 46 per cent. The result of operation in cerebral tumors is more favorable than in those located in the cerebellum. Even in cases where we are unable to definitely locate the growth, exploratory operation seems to be justifiable when the hopelessness of the case is considered. The opening of the cranium frequently relieves the suffering of the patient by reducing the intra-cranial pressure.

Brain tumors which can be diagnosed and located in the accessible parts of the cerebral cortex should be exposed by operation after a thorough course of medication. If the tumor is circumscribed, hard and superficial, the prospects for a cure are good. In operating upon cysts it is necessary to remove its walls to prevent recurrence. Filling the cavity resulting from operation with goldfoil, as advised by Estes (*JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*, 1896) has not been sufficiently practiced to render its general use advisable.

Epilepsy.—Two forms of epilepsy are amenable to operative treatment: Jacksonian and traumatic. General epileptic attacks, unaccompanied by a definite premonitory aura and in which the convulsion does not begin in any particular group of muscles, are generally not amenable to operative treatment, since one of the preliminary requisites to successful brain surgery, definite location of the lesion, is absent.

When the convulsion uniformly begins with a spasm in a distinct group of muscles or adjacent groups, trephining is a justifiable procedure. Any lesion which causes stimulation or compression of any area of the cerebral cortex may cause epilepsy. The various forms of meningitis, cysts, new growths, localized hemorrhage, arterio-venous aneurism, circumscribed encephalitis, and bone fragments are the principal sources of irritation. The large majority of these may be traced to some trauma, although there may be no external evidences of it. In addition to these cases, resulting from some local disease, we find a class which results directly from trauma. Wounds of the head are much more frequently followed by epilepsy than wounds of other parts of the body. This is especially noted where there has been injury and depression of the skull which has been expectantly treated. A cicatrix of the scalp may be the source of sufficient irritation to produce epilepsy, in which case its removal may effect a cure.

In cases where the location of the trauma can be definitely located, but in which the epileptic attack begins in another region, it is best to expose the focal area involved, and if no lesion is found the point of injury can then be trephined. It will frequently be practicable to expose both areas in the same opening. Some surgeons also believe in trephining at the point of the trauma or depression, even when the attacks are not focal but general in character. This is especially feasible where the trauma is located in some region the function of which has not as yet been determined. In those cases of focal epilepsy in which no lesion is found on exploring the brain, it is advised by some operators to ascertain by faradic stimulation

the exact point from which analogous movements originate and to excise it. The resultant paralysis gradually disappears if the area removed has been small.

The results of operations for epilepsy have not been as encouraging as we had reasons to hope for. Starr explains this fact upon the theory that the disease of the brain can not always be eradicated, and that while we can break up adhesion and remove scar tissue, the healing process results in the formation of new adhesions and new scar tissue; the new conditions resulting in the return of an epilepsy which may for a time have been apparently cured. Many operators seek to prevent the adhesion of brain to meninges and bone by the interposition of a sheet of gold foil (Park). Abbe and others have used rubber tissue successfully.

The writer, not long since, operated upon a patient for the closure of a bone defect resulting from a former trephining, for epilepsy, in which several strips of rubber tissue had been interposed between the membranes. The individual strips were found completely surrounded by scar tissue and the ends of two had been transposed to the outer side of the skull. Had a large single piece been used instead, the scar tissue would undoubtedly have been less, and the adhesion to the periosteum more likely prevented.

Indiscriminate operating upon the brain for epilepsy should be discouraged, but, on the other hand, in recent cases of traumatic epilepsy with distinct focal symptoms, the operation is not only admissible but should be strongly advised. The earlier the operation after the development of epilepsy the better the prospects for cure.

The statistics concerning a procedure, the technique of which is being constantly improved, are of but little value, except when confirmatory in character. Operations for epilepsy during the past few years are more successful than those made in preceding years. So many cases have been reported in the various standard medical journals, by reputable surgeons, that there can be no question but that many cases have been permanently cured, and as it is yet impossible to differentiate, without operation, between the various pathologic lesions, and especially since the mortality of trephining is very small and the number of recoveries on the increase, the operation is surely a justifiable one in proper cases.

Hydrocephalus.—Tapping and draining the ventricles through a trephine opening has been carefully considered by Keen, who was the first to tap the ventricle in this country, and others (*Medical News*, 1888). The object of the procedure being to relieve symptoms due to marked intra-cranial pressure, its scope is necessarily very limited. It may result in the cure of a primary case of hydrocephalus, as in Broca's case ("Brain Surgery," Starr) and that of Parkin (*Lancet*, No. 3664). As a palliative procedure it may be occasionally indicated during the course of a cerebral tumor, etc. When indicated it should be performed through a small trephine opening placed one and one-fourth inches above and one and one-fourth inches behind the external auditory meatus. A trocar should be introduced and a capillary or tubular drain inserted.

Imbecility and microcephalus.—Operations for the relief of these conditions have been performed with some degree of success; serious symptoms have been relieved and in some cases cerebral development has apparently been stimulated. In cases of arrested

development as from the presence of clots, cysts or tumors, or where premature ossification of sutures has occurred, operation may improve the condition of the patient. It should never be performed in patients over 8 years of age or in those especially weak. The cases in which an operation is justified are very rare. A sufficient number of cases have now been subjected to operation to definitely settle the fact that most of these unfortunate patients are beyond the relief of surgical treatment. An occasional brilliant success will, however, keep the profession awake to its value and, even admitting the hopelessness of this class of cases and the dangers of the operations, it is certainly a proper procedure in a small select class of cases. While Park and others believe that if one in twenty are rescued it is to be advised, Senn and others believe the procedure unwarrantable. The operation—craniotomy or craniectomy—should be extensive but preferably on one side at a time. Park prefers elevating the scalp and pericranium at one time and on a subsequent day removing the strip of bone and corresponding periosteum; this plan shortens the operation and lessens the mortality from shock, etc.

Insanity.—In cases in which mania has followed a definite trauma, which can be positively located, and in which the symptoms do not improve within a reasonable time and under appropriate medical treatment, the patient should be subjected to an exploratory operation in the hope of finding some removable cause for the symptoms presented.

Trifacial neuralgia.—This subject is merely mentioned because the removal of a part of the Gasserian ganglion requires the opening of the calvarium. The uniformity with which sections of the distributing branches of this nerve are followed by a return of the symptoms had induced some operators to advocate the removal of the Gasserian ganglion as a primary operation. As yet, this is not a justifiable procedure, but as a secondary operation for the treatment of inveterate, recurring tic douloureux it is certainly warranted. The basal method of Rose has been superseded by the Krause-Hartley osteoplastic flap operation. The ganglion can be readily reached by an opening in the temporal region, which admits of elevation of the temporal lobe. It is impossible to remove the first division of the nerve without injuring the cavernous sinus and adjacent nerves. The other divisions can be divided and removal of much of the ganglion by divulsion readily effected. The procedure is very difficult and the mortality is large, but in severe cases it should be advised. Nerve union by regeneration has been prevented by Abbe by the interposition of a small piece of aseptic rubber tissue ("Annals Surgery," Vol. xxv).

Operation of trephining.—This operation formerly indicated the use of the trephine only, but by common custom it now includes opening the skull by any method. It is performed for the following purposes: 1, for the relief of compression from depressed bone, blood clot, abscess or serous effusion; 2, for relief of intra-cranial irritation; 3, for the removal of tumors; 4, for defective development; 5, for the removal of foreign bodies; 6, for the removal of the Gasserian ganglion; 7, for exploration.

In no class of operations is absolute asepsis so imperatively demanded as in brain surgery. The scalp should be prepared by shaving and thorough disinfection with soap and ether twenty-four hours before the operation, if possible, and the wearing in the

meantime of a dressing of 1–2000 bichlorid solution. The parts should again be disinfected after anesthesia has been produced. Chloroform preceded by the hyperdermic administration of a liberal dose of morphin should be preferred to ether, as it causes less cerebral stimulation and congestion. One of the essentials to successful operative work is the location of the important centers on the surface of the scalp. The fissures of Rolando and Sylvius should be carefully outlined on the surface of the scalp and the points should be indicated on the bones by the punctures of a drill. The fissure of Rolando is outlined by a line three and one-half inches long, drawn at an angle of 67 degrees to the median line, from a point 56 per cent. of the distance backward from the glabella (root of nose) to theinion (external occipital protuberance). For practical purposes the line begins one-half inch behind the point midway between the root of the nose and the occipital protuberance. This line, with the proper angle, can be readily outlined by folding a piece of paper so as to make an angle of 45 degrees, and then 22.5 degrees which, added together, makes the requisite angle of 67 degrees. The fissure of Sylvius is located in a line drawn from a point one and one-fourth inches behind the external angular process to a point three-fourths of an inch below the most prominent point of the parietal bone. For general purposes the line drawn from the external angular process to a point three-fourths of the distance backward from the root of the nose to the occipital protuberance will make the line of the Sylvian and the external occipito-parietal fissures, the fissure of Sylvius beginning one and one-fourth inches behind the external angular process. Reid's baseline is drawn from the inferior margin of the orbit through the external auditory meatus. It is frequently utilized in locating the above-mentioned fissures. The incision should invariably be of the horse-shoe shape with the base downward toward the source of blood supply; the same to be modified as necessity may indicate. The opening in the skull can be made with a trephine and enlarged if necessary by the use of a rongeur forceps, a propelled circular saw or by the chisel and mallet. Each has its special indications and use, but the use of the chisel and mallet is undoubtedly increasing in favor. The special advantages of this method are the ready accessibility of the instruments; the method permits of making any shape and size of section; admits of preserving the nutrition of any sized section; is easy of performance and is a safe method, being practically free from danger. The dura should be opened at least one-fourth inch from the edge of the bone so as to admit of suturing latter. Hemorrhage from the diploe can be controlled by crushing, by plugging with decalcified bone or with Horsley's aseptic wax. Hemorrhage of the pia mater can be controlled by clamps, ligature of vessels, or pressure with gauze compresses. Park advocates the use of 5 per cent. solution of antipyrin. The brain can be safely explored with the exploring trocar. Incisions in the brain should be made with the scalpel. Cavities should be filled by gauze packing. Adherence of the brain to the dura or of dura to superficial scar can be prevented, it is claimed, by the intervention of gold foil, as advised by Beech of Boston, or by the use of rubber tissue, as practiced by Abbe, or of a thin celluloid sheet, as employed by McCosh ("Annals Surgery," Vol. xxii).

The opening in the skull can be closed by various

methods. A trephine opening can be closed with the removed button properly supported, or by the implantation of small fragments of bone, or bone saw-dust, or the outer table of another area of the skull can be loosened, but left attached to the periosteum and transposed to cover the defect (Nicoladoni; "Ann. Surgery," Vol. xxiii). Bone chips can be obtained by the use of the chisel or gouge on the adjacent sound bone, and should be placed on the dura, as a mosaic, with the outer side downward. These plans are known as autoplasty. By heteroplasty is meant the insertion of a piece of foreign material, as celluloid or aluminum. All of these methods are valuable and the circumstances will necessitate the use of each at times. In the replacing of large and numerous fragments after extensive fractures of the skull I have repeatedly made a satisfactory support, by making a frame work of catgut strands, which are placed in the periosteum loosely, forming a mesh not unlike loose darning. Undue pressure and unevenness can thus be readily prevented. The indications and conditions of each case must decide the question as to the use of drainage. Where there is doubt it is best to leave the wound open or provide for the free exit of blood, etc., by drainage.

ORIGINAL ARTICLES.

OBSTRUCTION OF THE BOWELS.

Presented to the Medical Association of Missouri, May 20, 1897.

BY T. F. PREWITT, M.D.

PROFESSOR OF PRINCIPLES AND PRACTICE OF SURGERY, MISSOURI MEDICAL COLLEGE; SURGEON TO ST. JOHN'S HOSPITAL, ETC.
ST. LOUIS, MO.

"Obstruction of the bowels" is a technical phrase which implies a mechanical obstacle to the onflow of the intestinal contents. Its causes are various and the obstruction may be complete or partial, acute or chronic. It may occur at any portion of the intestinal tract from the duodenum to the rectum. It may be due to conditions that are congenital or may be acquired. But whatever may be the character of the obstruction the one striking fact dominates all considerations relating to treatment—it is a mechanical obstacle. A simple reference to the schedule of causes, revealed by postmortems, establishes this fact and demonstrates as well the utter uselessness of medical measures.

It is impossible here to more than outline the symptoms, diagnosis and treatment of obstruction of the bowels, acute and chronic. It is necessary to deal with these two groups separately.

In the classification of intestinal obstruction it is necessary to take into consideration both the pathologic anatomy and clinical aspects of the subject and study the relations of one to the other.

A careful collection of a large number of cases examined postmortem has shown that one of the following causes is responsible, with rare exceptions, for every case of obstruction with which we meet: 1, internal hernia; 2, twists (volvulus); 3, bands of some kind; 4, fecal impaction; 5, mechanical pressure of tumors; 6, stricture; 7, contractures due to matting together of intestinal coils from peritoneal and cancerous diseases; 8, intussusception; 9, gall stones; 10, enteroliths; 11, foreign bodies. A more practical classification, however, is that in which all cases are divided into acute and chronic.

A study of the pathology in connection with the clinical history reveals a striking relationship between the causes and the group of symptoms which are associated with them. Thus, of the causes leading to acute obstruction we have: 1, internal hernia; 2, twists (volvulus); 3, bands; 4, intussusception; 5, gall stones. Of the leading causes of chronic obstruction we have: 1, fecal impaction; 2, mechanical pressure of tumors; 3, stricture; 4, contractures; 5, intussusception, which may be and is sometimes chronic.

So constant is the relationship between primarily acute obstruction and the causes grouped above that we can say that any given case is due to one of these, and the same may be said of primarily chronic cases.

Symptoms.—In acute cases these come on suddenly in a previously healthy individual and are striking and characteristic. The attack is sudden and acute. Pain is paroxysmal, central and fixed. Vomiting sets in early, first of the contents of the stomach, then of the duodenum, then of the small intestines and rapidly becomes fecal. The patient becomes faint, pale and markedly collapsed; constipation is absolute, not even flatus escaping from the bowels. Distention of the abdomen rapidly takes place and distended coils of intestines may often be both seen and felt. The urine may be scanty or even suppressed.

It will be seen that these are the symptoms of acute strangulated hernia. And why not? There is the same interruption to the onflow of the intestinal contents, the same obstruction to the blood current; the same disturbing and depressing effect on the nervous system, the same violent peristaltic action in the endeavor to overcome the obstruction and push on the obstructed contents, the same paroxysmal pains and eventually the same fatal result from precisely the same causes.

When, therefore, we are confronted with a case presenting such a group of symptoms there can be no doubt as to the diagnosis. A dire disaster has befallen the patient. Death confronts him and only the coolness, the courage and skill of the surgeon can rescue him from its grasp.

The bowels do not move. Shall we give purgatives? Already the bowel is making frantic efforts to force the blockade. Shall we stimulate it to more furious efforts to accomplish the impossible? No. It would be gross malpractice.

The patient suffers great pain. Shall we give opium? If it be used only as an adjuvant to annul pain, to relieve collapse, to restore the action of the kidneys, if it is administered for these purposes only while the surgeon prepares to relieve the strangulation, yes. If it is given with any curative purpose, then emphatically, no. We do but invite euthanasia. The patient relieved of his suffering is deluded with the idea that he is doing well, the doctor no longer assailed by the cries of the patient, too often hesitates and the golden moments slip by, during which the patient might be rescued from an otherwise inevitable doom. When the diagnosis is once made every hour of delay is compromising his safety. The bowel is damaged, peritonitis sets in, collapse ensues and the patient dies in spite of the delayed operation.

When the diagnosis is made celiotomy is the only thing consistent with that condition. If there be any doubt an exploratory celiotomy should be done to remove that doubt.

It is scarcely worth the time to discuss certain measures that are advised in these cases. Of what use is

irrigation or lavage of the stomach except for the purpose of putting the patient in a better condition for operation or distention of the colon with fluids, except for the same purpose. Tubage of the colon is a delusion; manual exploration of the rectum is a bit of brutal manipulation rarely justifiable. Taxis and massage, though lauded by that master in surgery, Jonathon Hutchinson, is useless and dangerous. Compression of the abdomen is a waste of time. None of these are curative and they but serve to divert the attention from the one thing that can relieve the difficulty.

I have been thus earnest in advocating early operation in these cases because I have seen them treated by the exhibition of the most powerful purgatives, by the administration of a quarter of a pound of liquid mercury, by delay extending over days, until the onset of peritonitis, the moist clammy skin, the hic-cough, the stercoraceous vomiting, the quickened pulse, proclaim any operation useless.

A few words must be said in regard to the differential diagnosis and treatment of acute intussusception, for while it presents the usual symptoms of obstructions of the bowels, there are certain symptoms peculiar to this accident. By the term intussusception we mean the inversion or prolapse of a portion of the bowel into the lumen of the part immediately adjoining. No portion of the bowel is exempt from this accident, though the relative frequency varies in different portions of the bowel. In the inversion of the finger of a glove we have an exact representation of what takes place in intussusception, except that in the inversion of the bowel the mesentery is carried in with the intussusceptum.

The rôle played by the mesentery is important. As the invagination extends the traction upon it increases, the tumor of which it forms a part is rendered somewhat crescentic, the pressure on the lumen of the bowel is increased and the facility of its reduction greatly interfered with. The most frequent variety is the ileocecal, the next the enteric, then the colic, while the ileocolic is the least frequent.

It is well to remember that intussusceptions occur in the dying. But as they give rise to no symptoms during life, indeed are discovered only postmortem, they do not concern the surgeon. The absence of all indications of congestion or inflammatory action and the facility with which they can be reduced render the diagnosis postmortem easy. In intussusception the constipation is not so absolute except in the very acute cases. A certain amount of diarrhea at the onset is frequent in a large proportion of the cases, constipation becoming complete toward the close of the case.

In consequence of the great engorgement of the invaginated portion of the bowel (the intussusceptum) a certain amount of blood is found in the stools. Tenesmus is a striking and usually an early symptom and the occurrence of marked tenesmus with bloody mucus in connection with other symptoms of obstruction is almost pathognomonic. It is often mistaken for dysentery. Vomiting is usually not so marked or distressing a symptom in intussusception. The presence of a tumor formed by the invaginated bowel can in nearly 50 per cent. of the cases, be felt. It can more frequently be recognized in children than in adults and is somewhat sausage-shaped. It is most often to be felt over the transverse and descending colon. When it can be found it is a great aid in diagnosis.

In the ultra acute cases death follows within twenty-four to forty-eight hours; they are always fatal, in fact. Fortunately the ultra acute cases are rare.

As to the treatment, I have succeeded in relieving quite a number of cases by distending the lower bowel with air or gas. I believe that an early resort to this method, before adhesions between the different layers of peritoneum have taken place, will often prove successful. Failing in this, an early resort to celiotomy is demanded to reduce the invagination. This is much more readily accomplished before the great engorgement of the invaginated portion has taken place and peritonitis with adhesions of the peritoneal folds has set in.

The reduction of the invagination is best accomplished by a process of pushing the intussusceptum out from below while slight traction is made from above. A direct pull on the invaginated portion of the bowel is apt to lead to tearing of its walls, and the danger is the greater the longer the invagination continues. Obstruction in some of its forms is by no means infrequent nor is the diagnosis always easy. In fact, judging from the injudicious treatment adopted we must believe that the true condition is not recognized or at least not appreciated in many cases. Postmortem investigations have thrown a flood of light on these cases and every fairly-well posted practitioner should be familiar with their pathology.

While it would be desirable to make a differential diagnosis as to the clinical cause in every case, it can not be expected to do more than approximate the special cause in a given case. Nor should it influence the course to be pursued. The suddenness with which appendicitis develops, the severity of the pain, the tendency to collapse and the occasional vomiting might mislead the practitioner and lead to some confusion as to the diagnosis as between obstruction and that disease. But the consideration of a few points of difference ought to clear up the diagnosis.

Appendicitis is an inflammatory affection *ab initio*. In obstruction, inflammation is a secondary affair.

The peritoneal irritation developed in appendicitis often causes great tenderness all over the abdomen, most marked, however, over the region of the appendix, and later receding until it is limited to that region.

Pressure over the abdomen in obstruction often adds to the comfort of the patient.

The pain in appendicitis is more continuous and localized. In obstruction it is central and paroxysmal. Vomiting in appendicitis is by no means constant. In obstruction it is rarely absent. In short, the arrest of peristalsis resulting from inflammatory conditions leading to a quasi obstruction has no place in this discussion.

Internal hernia must be reduced, volvulus must be untwisted, bands must be divided, etc.

Chronic obstruction of the bowels is marked by symptoms quite distinct from those of the acute. It will be found generally that there is a history of long standing trouble of the bowels, some colicky pains, difficulty of getting the bowels to move, and there may be blood or mucus in the stools and a change in the form and character of the passage. At one time diarrhea may be present, at another constipation, etc. These symptoms gradually increase in severity until the patient dies from exhaustion, or it may be acute symptoms supervene upon the chronic and the patient dies from collapse or peritonitis. The history is

one of chronic obstruction and though the patient may have, when seen, tympanitic distention, paroxysmal pain, visible peristalsis, vomiting, hiccough, etc., the cause will be found to be one of those I have enumerated, viz.: fecal impaction, pressure of a tumor, stricture of the bowel or contractions.

The most frequent of these is stricture of the large or small intestine. About 60 per cent. of the cases of chronic obstruction from all causes, examined post-mortem, have been found to be due to this cause, only 25 per cent. having been found in the small intestines, showing an immense preponderance in favor of the large bowel. In fact, it may be said that stricture is the cause of obstruction in the large bowel while "contractions" are the almost invariable cause of obstruction of the small. Strictures are, with few exceptions, cancerous and epithelial in character.

In a table of ninety-eight cases, compiled by Treves, the relative frequency of the different portions of the large bowel involved was as follows: Rectum and sigmoid flexure, 58; descending colon, 11; splenic flexure, 7; transverse colon, 7; hepatic flexure, 9; ascending colon, 2; cecum, 4.

The symptoms of stricture are alternating constipation and diarrhea, frequent mixture of blood and mucus with the stools and pain in defecation. When low down in the rectum the tumor can be felt with the finger, a means of diagnosis that should never be omitted. When in other portions of the colon it may often be felt through the abdominal parietes. The abdomen may be distended and, when distended, is most marked in the lumbar and epigastric region, in short, in the line of the large bowel. Large coils of distended bowel with visible peristalsis are often seen, the result of the hypertrophy of the muscular coat, brought on by the increased peristalsis, extending over a long period of time, to overcome the resistance offered to the onflow of the intestinal contents.

The treatment of stricture of the colon depends somewhat on its location. If it be the rectum, extirpation of the entire growth at an early period is the remedy. If higher in the bowel resection in favorable cases, and when this measure is impracticable, colotomy at a point above the stricture is indicated.

"Contractions," so named by Fagge, are a cause of obstruction in the small bowel and due to the matting together of the coils of the intestines from peritoneal and cancerous disease. In these cases the normal peristaltic action of the bowel is interfered with by the adhesions of the adjacent coils, by the bending and doubling of the bowel upon itself, thus interfering with the passage of its contents. This leads to the griping colicky pain often associated with the sick stomach coming on an hour or more after the ingestion of food and during the passage of the chyme through the obstructed portion of the bowel. Some distention may occur during the attack and, if so, is central and hypogastric; in other words, in the region occupied by the small intestines. The intestines will be seen writhing and coiling, a gurgling produced by the movement of the gases, and distinct peristaltic movements are perceived. With the escape of the contents through the obstructed portion of the bowel the patient is relieved of pain and discomfort until after the next meal, when the same symptoms recur. As there is no trouble with the large bowel the actions are normal and painless.

Something like 30 per cent. of the cases of chronic obstruction are due to this cause. The treatment

must be plainly palliative, consisting in a careful regulation of the diet and the administration of mild laxatives. Should the symptoms become more urgent and the suffering great, enterotomy should be done and an artificial anus established.

As regards the obstruction caused by tumors, the treatment resolves itself into the treatment of the tumors themselves, though colotomy may be required in certain cases.

Last but not least in importance are those cases of obstruction due to the accumulation of feces. The importance of examining the rectum in all cases of obstruction of the bowels is emphasized in these cases. A source of error in the diagnosis in this condition is the fact that a quasi diarrhea may exist. While the bowel is loaded with fecal matter, a channel may be furrowed by the side of the mass, by which the thinner contents of the bowel higher up make their way and escape from the anus. It is not a rare thing to find that the practitioner has administered anodynes and astringents to control this supposed diarrhea.

The foundation of this condition is an habitual constipation brought on usually by sedentary habits, neglect of the individual to heed the desire to act, a gradual diminution of the reflex excitability of the spinal centers and such a stretching of the bowel that it fails to take cognizance of the presence of fecal matter.

This chronic constipation may lead to that condition known as "ileus paralyticus," in which a considerable portion of the bowel may become incapable of peristaltic action and absolute obstruction occurs. A mass of fecal matter accumulates in this section of the bowel and the portion above is incapable of exercising sufficient force to push it along. With time the accumulation becomes harder and harder, the bowel below has a tendency to contract and adds to the difficulty of emptying it. The continued accumulation of fecal matter distends the bowel still more until rupture may take place. Ulcerations are frequent and peritonitis may develop. Like all other forms of chronic obstruction the symptoms are likely to become aggravated and eventually to become acute.

The length of time during which the bowel may remained blocked is in some cases astounding. Dr. Thos. Strong reports a case in which no evacuation took place for eight and a half months. The extent to which the colon may become distended is very great. In a case which I saw some years ago, a prominent business man of this city, the whole colon from the cecum to the sigmoid flexure was filled and it could be felt as a large roll movable laterally, swinging upon the meso-colon, and evidently several inches in diameter. The presence of such a mass in the large bowel is a diagnostic feature of great value. In the descending colon and sigmoid flexure this accumulation may be divided into scybalous masses, forming what has been compared to a large rosary.

Would any one regard the use of purgatives as a rational method of treatment in these cases? I think not. It would not only be useless but as illogical as an attempt to force out a cork from a bottle by explosives from within that might more readily be extracted by a corkscrew.

The treatment of these cases should consist in the repeated and copious enemata of warm water, with or without the addition of other ingredients such as tur-

entine, soap, oil, etc. To be effective the enemata should be introduced slowly with the patient in the knee-chest position, so that the fluid may traverse the whole length of the colon. Massage may be resorted to advantageously as well.

Cases occur where none of these measures prove effective in breaking down and dislodging these fecal masses and the symptoms of obstruction persist. The surgeon is then left the alternative of opening the abdomen and, by direct manipulation of the bowel, compressing and pushing on the accumulation to a portion of the intestine still capable of peristaltic action.

Should the existence of ulceration or peritonitis or other conditions forbid such a course, colotomy would be advisable, removing the fecal matter through the opening and subsequently stitching it up or establishing an artificial anus as might seem best.

In conclusion I would submit the following propositions:

1. Purgatives are absolutely contraindicated in all cases of acute obstruction, and are of very limited, exceptional and temporary advantage in chronic cases.

2. The administration of opium as a remedial agent is to be strongly condemned. It literally "smooths the pathway to the grave," lulls to sleep and lures to death.

3. Obstructions of the bowels are strictly surgical and demand surgical measures for their relief.

NOTE.—In the preparation of this paper I have been indebted to various sources for valuable suggestions, especially to the essay of Mr. Frederick Treves of London on "Intestinal Obstruction."

RAILWAY SPINE AND LITIGATION SYMPTOMS.

Presented in the Fourth Annual Meeting of the American Academy of Railway Surgeons at Chicago, Ill., Oct. 6-8, 1897.

BY W. W. GRANT, M.D.

SURGEON CHICAGO, ROCK ISLAND AND PACIFIC RAILWAY.
DENVER, COLO.

From a certain class of spinal symptoms and nervous manifestations following and believed to be typical of railway accidents, is evolved the use of the term "railway spine." The pathologic lesion is not essentially different from similar lesions occurring under other circumstances and conditions, and the term may not be a happy one.

The element of fear enters largely into these histories. There is a distinct appeal to the mental and emotional, and with a certain similarity in clinical histories and results they have been, and are by many at least, believed to be peculiar to railway collisions; so we are justified, as railway surgeons, lawyers and neurologists, in giving them special consideration. We are, perhaps, familiar with those interesting cases following collisions, called often "spinal concussion," in which there is no evidence of a pathologic or anatomic lesion, by any clinical or scientific tests at our command, but in which the patient complains of persistent pain at some point of the spinal column, attended with various nervous manifestations due to the "shock." These cases never recover until there is a definite financial disposition of them. To such cases, an English jurist has applied the term "litigation symptoms."

The teaching of Mr. Erichsen in applying the term "concussion" to all the structures of the spine is too

indefinite in history and pathology, and as it does not represent the best thought and opinion of our time, can not be accepted. Concussion of the cord is definite and satisfactory. The cord is so well protected by its environment that concussion is very rare, though believed to be common from railway collision.

Actual lesion of the cord from injury is usually fatal, and when it does happen it is usually attended with direct and manifest injury to some or all of the overlying structures. Meningitis from concussion is equally rare and usually fatal, from whatever cause. It is not with these and the unmistakable injuries of the spine that surgeons, neurologists, railway attorneys and corporations, have the most trouble. When the surgeon is confident of a serious lesion, his plain duty to both patient and corporation will often prevent lawsuits. Whether his conclusion is just will depend very much upon the character and completeness of his examination. We can not rely too confidently upon our instruments of scientific precision. The dynamometer, esthesiometer, audiometer, ophthalmoscope, battery, etc., can be weakened by elements of fraud and deception. Mr. Page says plainly that "nothing has struck us as more extraordinary in our experience of railway injuries than that in the examination of them all common sense, the best and surest diagnostic guide, should be so often abandoned and reliance should be rather placed on methods of examination which are of scientific value only when every suspicion of exaggeration or imposture can be put away."

Only a few years ago it was said "no electric test has yet been found which is not rather a test of the credulity of him who trusts it." There is much truth in the statement. The reactions of degeneracy can be proven and the test is often of much value, but only in the hands of a scientific expert, who is equally familiar with the nervous and muscular conditions sought to be elucidated. The manner of the examination is often defective and unwise. I have known these examinations to be conducted in such a way as to suggest to the patient symptoms and ideas that he had not thought of before. An intelligent, shrewd or dishonest individual will utilize them to his own advantage and sometimes to the annoyance of the medical witness and expert.

Not only a full account of the nature of the accident, but the history of the patient prior and subsequent to it is of the greatest importance. The previous condition of health, the vocation, moral status, mental bias, the conduct and character are legitimate matters of surgical inquiry and often necessary to an intelligent and satisfactory explanation of the case.

Erichsen in his work on spinal concussion uses this language: "An extensive experience in railway compensation cases will probably impress you more with the ingenuity than with the honesty of mankind. A history of deception, practiced on railway companies by alleged sufferers from accidents on their lines, would form a dark spot on the morality of the present generation." Yet, the writings of this distinguished surgeon gave more character to such claims than any other single agency in this generation, though he did not so intend. I believe the statement of Mr. Page true that "molecular disturbance is not necessarily molecular disintegration or pathologic change, and there is no evidence to show that molecular disturbance is, in itself, a grave condition or likely to have evil results." Otherwise it would be something fearful

to contemplate the menace to the individual and to the employer from the effects of a jar to the nervous system.

We now know that the serious results from railway collisions are manifested at a very early date after the accident: and in those cases where the symptoms were insignificant or so slight as not to attract the special attention even of the patient and yet at a more remote date, weeks, months or years, serious symptoms present themselves, it will generally, I believe, be found that some constitutional infection, such as syphilis or tuberculosis, is the chief factor in the case. And this is as true of the nervous as of the bony and glandular systems.

We hear now of traumatic hysteria: of the neurosis resulting from shock or injury to the nervous system. Obersteiner has recently said, "where we had hoped to establish a firm anatomic basis, there was only an undemonstrable functional injury of the nervous system, but it is going too far to regard all cases formerly considered as concussions of brain and spinal cord, as purely functional." This is, no doubt, true. It is just as true that most of the spinal cases, so commonly called concussions, are not concussions at all; but if any injury really exists, it is contusion or muscular or ligamentous strain. Many of these cases do not recover promptly, but require considerable rest of the parts. They will recover perfectly, however, unless the patient is imbued with the idea that serious results are quite certain to follow "concussion of the spine" from railway accidents.

Under former professional teaching, the opinion, professional and lay, was quite general that the slighter injuries, called usually concussion of the spine from railway collisions, frequently developed at a later period, serious symptoms often with unfortunate results. This is true only exceptionally. But with real concussion of the cord there are generally other unmistakable evidences of injury, and we are enabled to form an intelligent and more satisfactory opinion as to the future.

Concussion of the cord being the exception and not the rule from railway collisions, we ought to leave the unfortunate errors of the past. It is desirable, as soon as possible, to establish the results of railway injuries to the spine upon a pathologic basis. Deferred shock, of which we hear something, is like some of the manifestations of hysteria, emotional or mental. Those cases with slight complaint or manifestations of injury following railway collisions do not, as a rule, at a late day assume a grave form, but they are apt to become litigation cases.

Our experience with such cases, out and in courts of justice, may be commonplace yet beneficial, and I will give one experience:

Three years ago a Denver woman, aged 34, milliner, was on a Rock Island Pullman car at the time of a collision in Kansas. The immediate attendance of railway officials and a local surgeon discovered no passenger injured or complaining. When the lady reached Denver next day, she sent for her physician, who found her with a slight cold only and did not return. In a day or two the company requested me to visit her and report. Recording the result, I found pulse, temperature and pupils normal and no disturbance of motion or sensation general or special, reflexes normal, but when bending her head and shoulders forward, also on pressure, she complained of pain in the upper dorsal region, but there was no discolora-

tion or evidence of a blow. At time of collision she was asleep, but says her head struck against the head-board, partially doubling her up (which with head toward engine is not improbable). There was total absence of contusion anywhere, but such a position would favor straining or laceration of spinal muscles and ligaments. She came to Colorado eleven years before for supposed lung trouble but had been well ever since. I could discover only a slight cold, resulting probably from delay and absence of fire in a cold season. I gave her a favorable opinion, but from her manner I felt certain she would demand considerable money, so made two or three visits and then had her visit me at my office occasionally for several months, in order to watch developments. To be well prepared, a reputable nerve specialist examined the case at this time, applying all the usual scientific tests and finding no evidence whatever of disease. He asked if she observed any peculiar effects from riding in street cars and, of course she answered "yes." Something, I believe, like fear possessed her. She had never before been affected this way, and but for the suggestion of the examiner, I dare say would never have found it out. She demanded \$2000 from the company, was offered \$500, brought suit for \$15,000 and it was tried in the Federal court two years ago. Notwithstanding dry cupping and rest for two months following the collision, the spinal pain never ceased and she complained subsequently of headache and sleeplessness at times. The day before the trial she was carefully examined again by the neurologist and myself, and pronounced perfectly healthy. She was so well in her pelvic organs as not even to suggest curetting nor a thought of exploratory section. No symptom is of less value as indicating disease of the cord than spinal pain, yet it is ever present and often with varied and ill-defined nervous manifestations.

A year after the accident she testifies that she is not yet able to conduct her business. I testified that she was as healthy a woman probably as there was in Denver: that if suffering, it was from litigation symptoms and from these would not recover until the case was finally settled; that sometimes such condition of the patient was malingering for the benefit of the money consideration involved. With some claimants the feeling was honestly entertained that they were suffering from the effects of injury, and though they were generally mistaken in this, yet there would be no confession of recovery until the case was definitely settled. There can be no doubt that early settlement in undoubted injury favors earlier recovery.

The neurologist testified that this patient, in his opinion, was not suffering from any disease of the nervous system whatever, but when asked on cross examination to give an opinion on the claimant's own statement of her condition, he said, "she might have hysteria." "And is not hysteria a serious disease?" was instantly asked and he replied, "frequently, or sometimes, it is." This statement and that of her own physician, that he could find nothing the matter unless it was hysteria, was absolutely the only medical testimony given in her favor, and the only excuse the jury used, if indeed it needed any, for rendering a verdict of \$700 in her favor.

Hysteria as a neurosis, or as an expression of disorder of the generative system, is not a serious condition, and I have been often surprised that even medical experts would, upon the witness stand, use the same language and manner before an ordinary jury,

utterly ignorant of the subject, that might be justified before a body of scientific men. This discrimination is an absolute necessity, in the dispensation of justice, to all parties concerned. It is doubtful if a case of importance was ever tried without some medical witness saying something that was unjust to himself and damaging to his cause, and not infrequently because he wished to be supremely scientific and eminently impartial to a body of men incapable of appreciating his meaning.

I meet this woman frequently on the streets of Denver and I have no doubt of her excellent health and her attendance on business.

Within the last year, a Massachusetts lady was on one of the principal trains entering Colorado, when it collided with a snow bank, causing some delay but, on immediate investigation, no injury to any one. Some time after suit was brought against the road by the lady for deafness due to the collision, and the jury gave her a verdict of over \$2000. My attention was subsequently called to the case, and the railway attorney told me that he accepted the statement of the aurist who attended her only because "it seemed fair." He said no investigation was made as to her previous history, but that her character was a "little shady," and I ventured the opinion that her statement as to her ear trouble probably was also. If an investigation of her past history in Massachusetts had been made, it is not improbable that satisfactory evidence of previous ear trouble could have been obtained.

The medico-legal relations of these railway cases are of peculiar interest to the railway surgeon and the medical expert. The surgical treatment of actual railway injuries is governed by the same general rules and principles which prevail under other circumstances, but always with due regard to the peculiarities of environment. "With the character and manner of conducting these claims we have nothing to do," but it is as much our duty to understand, if possible, and to appreciate the motives and conduct of these claim patients, as it is for the lawyer to prove them. Generally when the clinical history and statements are at variance with those which we should most reasonably expect under ordinary circumstances, we are justified in suspecting ulterior motives, and these are usually of a financial character.

The hope and anticipation of reward consciously, and unconsciously perhaps, influences the course and conduct of individuals in different relations and positions and this is especially true when compensation for injury and lost time awaits those who are injured in the service of corporations, of which railways afford the most conspicuous if not the most peculiar example.

It is a matter of common observation that the class of patients under consideration are prone to exaggerate every symptom and fear, and if they are silent or their manner unusual upon the statement by the surgeon of a favorable and early recovery, it is safe to assume that a financial problem is under consideration.

How best to meet the actual and varied manifestations of railway injuries and their consequences, near and remote; to separate the imaginary from the real, the fraudulent from the honest claimant, and to properly estimate self-interest and the varied prejudices that enter into consideration *nolens volens* in the endeavor to reach a just solution, is a problem that appeals to the best thought, feeling and judgment of every interested party, and the unremitting labor of a learned profession.

DISCUSSION.

Dr. J. P. LORD of Omaha—This subject, which so much concerns railway surgeons, has been discussed from the beginning of our meetings. It is a question that will be with us just as long as we have to deal with human nature. Who has not been called in for no other reason than to cultivate the good graces of the doctor, and consult him for ulterior motives? Who has not been called in also by all kinds of designing people who have their particular axes to grind? This spirit pervades all classes of society. A man who draws a \$5 a week indemnity from a local lodge, perhaps on account of indiscretion, or because of a desire to get a day off and at the same time to help to bear the expense of this lay off, calls in a physician. What he wants is the doctor's certificate of his illness more than a prescription. Perhaps the prescription is never filled. So we might add to the list of people who will deceive the doctor if they can. It is difficult to deal satisfactorily with this question, as these people will always be with us. We can not reconstruct human nature; we can not make juries any different, but we can make ourselves wiser in handling these people and doing what we can toward conducting our case successfully and protecting our employers; so that while it is a question of scientific interest, yet it is one that will never be disposed of. For years it has been an interesting study to me to know why doctors could not handle a certain class of neuroathenics, people who would be seen in spite of the doctor, and who could not be cured by anybody but those who resorted to deceptive methods, and these deceptive methods seem to take the place of the green plaster in railway injury cases.

Dr. THOMAS B. LACEY of Council Bluffs—I presume that in order to properly qualify a surgeon to make a good witness he must be a man of experience on the witness stand as well as in his professional work; and still there are none of us who are willing to pose in the light of professional witnesses, for I believe, even in a surgical way, they will not have weight with a jury. We gain our experience on the witness stand by testifying, and must be willing to accept the name of professional witnesses if called sufficiently often to bring it about. But we should guard ourselves as much as possible in making admissions that we do not mean. The neurologist, on the witness stand, probably stated that he did not think there was anything the matter with the lady in question, but the lawyer succeeded in having him admit that she might have hysteria. There is a lesson in that point. These admissions weaken the case, and it is because of our little experience as witnesses that we are called upon to make admissions that we can safely do among our fellows, but not to a jury who have no conception of what we are willing to have understood by those admissions. As a general rule, it is a good safeguard, after you have examined your claimant and found that in your opinion there is nothing the matter with him, to so state it on the witness stand, and your opinion should be persisted in without any admissions or equivocations.

Dr. W. L. SMITH of Streator, Ill.—The best time to interview an injured person and get a truthful statement is at the time of the injury. We will get more truth then than we will after a shyster lawyer steps in. Get the statement and be ready to make your examination carefully and thoroughly, and state your opinion as to your findings, even though judge or jury be against you.

Dr. FRED J. HODGES of Anderson, Ind.—Every man on the witness stand should be honest with himself and in his opinions, and if he believes that there is nothing the matter with a case, and yet feels in his own heart that there is a possibility of it, he will still further bring expert testimony into contempt if he does not admit such a possibility of injury. If he is experienced as a witness his answer to that question will be something like this, that it is possible but not at all probable, and in that way he is honest without doing the case harm. I do not believe any member of this Academy would wish to be understood as saying that because a man is employed by a railroad and is called by that railroad to testify, that he should lose his scientific spirit and deny a possibility when one exists.

Dr. HAY who was professor of neurology in the Northwestern University Medical School, used to say to his class, "there are three things every medical witness must understand and be guided by. In the first place, never be afraid to say, 'I don't know.' If you do not know, say so. You will save yourself trouble and gain strength for your case. In the second place, never acknowledge authority for anything. You are called upon to tell what you know, not what anybody else supposes or knows. In the third place, be strictly honest and scientific all the time." If any medical witness will be governed by these three propositions I think there will be less reproach connected with the term "expert witness," and that the truth will not suffer.

MUTUAL RELATIONS OF THE RAILWAY SURGEON AND THE NEUROLOGIST.

Presented in the Fourth Annual Meeting of the American Academy of Railway Surgeons, held at Chicago, Oct. 6-8, 1897.

BY J. T. ESKRIDGE, M.D.

NEUROLOGIST TO ST. LUKE'S HOSPITAL AND PRESIDENT OF THE STATE BOARD OF COMMISSIONERS FOR THE INSANE ASYLUM, DENVER, COLO.

That the general surgeon and the neurologist should work together in the advancement of cerebral and spinal surgery is accepted by the best men of the profession. That the professional relations of the railway surgeon and of the neurologist should be more comprehensive and extend to nearly all cases of railway injury has not, to my knowledge, been generally recognized by the chief surgeons of the great railway systems.

A brief abstract from the reports of two cases of alleged railway injury will aid in bringing this subject before the Association for discussion:

Case 1.—J. R., in 1889, while climbing down from his upper berth in a Pullman sleeping car, was thrown to the opposite side of the car by some accident which caused the engine and one or two cars to jump the track. He was not rendered unconscious nor did he appear to be greatly injured. He told some fellow passengers and acquaintances who were on the car that his body felt sore and that he seemed dizzy. He got off the car and walked around the train for some time. On reaching Denver a day or two later he consulted one of the surgeons of the railroad company. The patient complained then of nervousness, sleeplessness, a headache and general discomfort in various portions of the body. On the surgeon finding no positive evidences of injury he soon dismissed the case as one of minor importance. The man became a semi-invalid, refused to work, as he said he was unable to do so on account of pain in his back. Six months after the accident he suffered from an attack of typhoid fever. After recovering from the fever he seemed to be in about the same condition of health as that which had preceded the typhoid attack. He consulted numerous physicians, and finally, on finding the right leg below the knee much smaller than the left, he began to limp and complain of pain in the leg. Two years after the accident a damage suit was brought against the railroad company.

At this time I was asked by the attorney for the plaintiff to examine the man. He walked with the assistance of a cane and exhibited a decided halt in his gait. Most of his former symptoms of nervousness had disappeared and he complained mainly of pain in the right leg and weakness of the muscles below the knee. The circumference of the right leg over the largest portion of the calf was nearly two inches less than that of the left. The tibialis anticus and peroneus group of muscles were the seat of the greatest amount of atrophy, but the calf muscles presented considerable wasting. All the affected muscles showed a decided lessening of irritability to the faradic current, and the tibialis anticus and peroneus longus presented the reactions of degeneration.

In short, all evidences pointed to poliomyelitis affecting the muscles of the right leg below the knee. All other symptoms that he then complained of were either feigned or greatly exaggerated. He positively stated that the right leg was perfectly normal before his fall in the Pullman car. He further insisted that the wasting had begun about a year before I saw him and that it had been steadily increasing. The electric changes were too pronounced for an ordinary case of progressive muscular atrophy, even of the peroneal type. It is well known, however, that we may have a focal poliomyelitis of traumatic origin, and from this gradual wasting of the muscles may ensue and result in a form of muscular atrophy of spinal origin. The

only way to determine this in the case under consideration was by watching the case for a year or more. A gradual increase of the trouble meant a progressive muscular atrophy which would ultimately prove fatal. I reported the results of my examination, together with my conclusions to the plaintiff's attorney. To my surprise, the lawyer did not hesitate to advocate the the gravest possible view of the man's condition. I argued with him that I could not say the trouble did not antedate the railroad accident many years, and that we had to depend upon the veracity of the patient, which was not good, in excluding a poliomyelitis dating from childhood.

The case was tried. I simply stated what I had found. The attorney for the plaintiff very shrewdly asked me no questions, further than to lead up to the fact that if the trouble had been progressive during the past year, as the patient stated, it would result in total disability and finally in death.

The attorney for the defense was an able lawyer, but ignorant of medicine. His efforts were principally directed toward showing that there was no spinal cord lesion. The physicians called by the defense had to admit there was some organic lesion. Again, to my chagrin, no questions were framed so that I could give my opinion in regard to the probable nature of the case. The man was awarded several thousand dollars damages. Before the case came to trial, as well as during the time of its progress, I learned that the man did not hesitate to pervert the truth when it suited his convenience, hence I suspected that the spinal trouble dated from childhood. Coloring was given to this view by the man never having complained of the right leg more than the left until muscular wasting was detected by a physician some time after the railroad accident. It evidently occurred to the man at the time the wasting was found by the unsuspecting physician that he had something definite on which to base a suit for damages, and he ceased to lay stress on his other troubles, mainly complaining of his leg.

I had an opportunity to study this case some two years after damages had been awarded the plaintiff. There had been no further wasting and the electric reactions remained the same as at the time of my first examination. I subsequently learned from one of the man's friends that he had been paralyzed during childhood and confined to his bed for some time.

The point on which I wish to lay stress is this: If a careful neurologic examination had been made at the time the man first consulted the surgeon for the railway, the poliomyelitis would have been detected and the company, in all probability, would not have been sued. Certain it is, that no damages would have been awarded had it been possible to prove that the accident on the railroad had had nothing to do with the condition of the man's leg.

Case 2.—R. E., age 52, traveling salesman, was well until 40 years of age (1880), when in a runaway, he was thrown from his carriage and injured his right shoulder. Six years later the right hand and arm began to be affected by a rhythmic tremor which was fine, most pronounced after exhaustion, but momentarily disappeared on moving the arm. In June, 1892, he had a severe attack of gonorrhea followed by cystitis. July 30, 1892, he was severely shaken up in a railroad accident on one of the Western roads.

He stated that up to the time of the accident the tremor had been limited to the right arm and hand and did not greatly interfere with his writing. Immediately following the accident his physician states that he had prostatitis, orchitis and cystitis with

severe pain in the back. Whether the shaking-up that he received on the road had anything to do with these inflammatory troubles is doubtful, as the man was addicted to the use of alcohol and was inclined to neglect himself.

Three days after the accident on the road, a tremor similar to that of the right arm and hand began to be manifest in the left hand. The right arm became worse and he wrote with difficulty. He remained in bed for thirteen weeks and was treated for bladder and other associated troubles. After he had been in bed some weeks he noticed that his right leg began to be affected by a tremor, and soon after this the left leg was involved.

A careful examination by me on Nov. 11, 1892, showed that the man was suffering from paralysis agitans. The right hand and arm had assumed the characteristic positions seen in this disease, the left hand remained constantly bent at the meta-carpo-phalangeal joints and the muscles that move the right leg at the knee were a little rigid. There was no rigidity of the muscles of the left leg. Tremor was well marked in the right arm and slight in the right leg and left arm. When he was excited there was a perceptible tremor in the left leg. Muscular weakness was pronounced in the right hand and arm, but in the other extremities muscular power was fairly well maintained. The patient was under my care for several months subsequent to Nov. 11, 1892. During this time the disease did not seem to make any progress.

A suit for damages against the railroad company was brought and the attorney for the plaintiff summoned me to testify in the case. I told him that the accident which had resulted in a few bruises on different portions of the body, had had nothing to do with starting the disease, but that it evidently had some influence in causing its extension. He seemed satisfied with this, but when I was on the witness stand he refrained from asking any questions, by answering which I could inform the jury that the man had been suffering from paralysis agitans for a number of years before the occurrence of the railroad accident in which he had been hurt. I was asked if I had examined and treated the plaintiff: from what he was suffering: the cause of paralysis agitans, and if an injury such as he had sustained in the railroad accident, was capable of giving rise to paralysis agitans or causing its rapid extension. I was not asked either by the attorney for the plaintiff or defense whether I knew or thought the accident in question had been the cause of the disease from which the plaintiff was suffering. The medical witnesses for the defense honestly admitted that the man was suffering from paralysis agitans, and as they knew nothing of his history they were free to admit that the injury received in the collision was the probable cause of the disease. The man was awarded \$7000 damages by the jury and the whole amount with interest was paid about eighteen months later.

How easy it would have been to prevent such an exorbitant award for damages had it been known by the attorney for the defense that paralysis agitans had existed for years before the railroad accident. The urethritis from which the man suffered a month or so before he was shaken up on the railroad was the probable cause of the cystitis, orchitis and prostatitis, but the attorney for the plaintiff made it appear to the jury that these resulted from the injuries received on the railroad.

It may be thought by some that I was in the wrong in not telling the jury that the nervous trouble from which the man was suffering antedated the railroad accident about six years. Witnesses are sworn "to tell the truth, the whole truth and nothing but the truth."

The understanding that I had with the plaintiff's attorney was that he only claimed damages for the rapid progress of the disease caused by the accident, and in consequence a probable shortening of the man's life by a number of years. The questions asked me by the plaintiff were absolutely fair. The principal one was: "May an injury, such as the plaintiff is alleged to have received, be the cause of paralysis agitans or result in its extension?" There could be but one answer to this. Up to the time of my cross-examination I believed that the attorney for the plaintiff intended only to put in the plea of exaggeration of the disease and shortening of life. As soon, however, as it was found that the attorney and witnesses for the defense knew nothing of the man's history previous to the accident of 1892, the way was open to claim that the railroad company was responsible for causing the disease. I had left the witness stand before I saw the turn the attorney for the plaintiff had made. I could not then interfere. Although a witness is sworn to tell the whole truth, yet the expert witness is usually limited to opinions at which he has arrived through special training in a particular line. Once, while on the witness stand testifying as an expert, I saw that the attorney who had summoned me in the case, by shrewd questioning was perverting the truth so as to make my testimony very unfair to the opposite side, and I requested an opportunity to explain, but the judge reminded me that it was the business of the attorney for the defense to look out for his client.

In the second case reported in this paper injustice to the defendant could have been prevented by the railroad company having had a careful neurologic examination made of the man's condition soon after the occurrence of the accident. A complete history of the man's health up to that time would have thrown light on the case.

I have not found that people who have been injured on a railroad object to a careful examination by a physician employed by the road, if the examination is proffered soon after the occurrence of an accident, before an attorney is consulted. It is at such a time that a fairly accurate history of the injured person's health can be obtained by the physician of the road.

The injured are at first anxious to ascertain the extent of their disabilities and the probable results of their injuries, and the more attention that is paid them by officials of corporations the more communicative and confidential they become.

I have been acting as consulting neurologist to one Western railroad for a period of about nine years, and during this time I can recall numerous cases of injury for which claims for damages without suits have been settled for nominal sums, because careful examinations of the injured had been made soon after the occurrence of the accidents. In numerous other instances suits for damages have not been brought, or if brought the parties have received no damages on account of the company being able to show that certain states of ill health antedated the accident in which the persons claimed to have been injured.

In conclusion, I wish to say that I believe every

railroad or large corporation should have a consulting neurologist, and that the chief surgeon of the road should insist that a careful neurologic examination be made of most of the injured as soon after accident as possible, especially in those cases in which there is likely to follow a suit for damages.

DIAGNOSIS OF TYPHOID FEVER.

Read at the Anniversary Meeting of the Calhoun County Medical Association at Battle Creek, Mich., Dec. 12, 1897.

BY A. W. CRANE, M.D.

KALAMAZOO, MICH.

The diagnosis of typhoid fever is a very modern achievement. A long list of diseases has been recognized by physicians from the time of Hippocrates, but the disease-entity which we call typhoid fever was not recognized as a separate disease until the early part of the nineteenth century. The name typhoid was bestowed upon it in 1829, but even then it was confused with typhus fever, and it remained for a distinguished American physician, Gerhard of Philadelphia, finally to differentiate it from all other fevers. This was in 1837. It was less than ten years before the discovery of anesthesia by ether. Pause and consider with what rapidity the science of clinical diagnosis has developed. Within the memory of physicians yet living, typhoid fever, now one of the corner stones of a medical education, was for the first time differentiated as a truly distinct disease. This remarkable fact allows one to doubt the reputed powers of close and keen observation in our medical forefathers.

However, we must recognize today the great difficulty of diagnosing the continued fevers from clinical symptoms alone. The cautious practitioner is wary of giving an early diagnosis. Long differential tables of symptoms still fail to give much certainty to his conclusions when he is called upon to decide in the beginning between such diseases as scarlatina and measles; tonsillitis and diphtheria; or simple continued fever, bilious fever, septicemia, miliary tuberculosis, malaria and typhoid fever. In the first days of almost any fever not accompanied by an eruption as in measles, or a local sign as in tonsillitis, the possibility of typhoid fever arises in the mind of the attending physician. He watches for an ascending pyrexia with morning remissions, a diarrhea, an abdominal tenderness, an enlargement of the spleen, and a rose-colored eruption over the abdomen; but he has to remember that the eruption is absent in 30 per cent. of cases and indistinct in half the remaining, that the enlargement of the spleen may be present in malaria and other diseases, that diarrhea may be absent or replaced by constipation, and that the fever curve has no constant characteristics whatever. So uncertain is the early diagnosis, that if the temperature drops on the tenth or fourteenth day the physician is often undecided in his own mind whether the patient really did have typhoid. If he has been shrewd enough not to have committed himself he is likely to call such a case bilious fever.

To illustrate the truly serious difficulty of making a differential diagnosis in some cases, at any stage, I will quote a few passages from Osler's "Practice of Medicine," second edition. He says (p. 33) "The early and intense localization of symptoms in certain organs is a frequent source of error in diagnosis. The following are the most frequent deviations from the normal course: *a*, onset with pronounced ner-

vous symptoms; *b*, with pronounced pulmonary symptoms; *c*, with intense gastro-intestinal symptoms; *d*, with symptoms of acute nephritis (p. 13). Cases coming on with severe headache, photophobia, delirium, twitching of the muscles and retraction of the head are almost invariably regarded as cerebro-spinal meningitis. I have thrice performed autopsies on cases of this kind in which no suspicion of typhoid fever had been present, the intense cerebro-spinal manifestations having dominated the scene. Fully one-half of the cases of the so-called brain fever belong to this category. Misleading pulmonary symptoms occasionally develop at the very outset of the disease. The bronchitis rarely causes error though it may be intense and attract the chief attention. More difficult are the cases setting in with a chill and followed rapidly by pneumonia. I have brought such a case before my class one week as typical pneumonia and a fortnight later shown the same case as undoubtedly one of typhoid fever. In another case in which the onset was with definite pneumonia, no spots developed; and though there were diarrhea, meteorism and the most pronounced nervous symptoms, the doubt still remained whether it was a case of typhoid fever or one of pneumonia in which severe secondary symptoms developed. There is less danger of mistaking the pneumonia which develops at the height of the disease, and yet this is possible as in a case admitted a few years ago to my wards; a man aged 70, insensible, with a dry tongue, tremor, ecchymosis upon the wrists and ankles, no rose-spots, enlargement of the spleen, and consolidation of his right lower lobe. It was very natural, particularly since there was no history, to regard such a case as senile pneumonia with profound constitutional disturbances; but the autopsy showed the characteristic lesions of typhoid fever" (p. 33-34).

"The differential diagnosis between general miliary tuberculosis without local manifestations and typhoid fever is extremely difficult. The cough may be slight or absent. Diarrhea is rare in tuberculosis; the bowels are usually constipated, but diarrhea may occur and persist for days. In certain cases the diagnosis has been complicated still farther by the occurrence of blood in the stools. Enlargement of the spleen occurs in tuberculosis, but is neither so early nor so marked as in typhoid fever. In children, however, the enlargement may be considerable. The urine may show traces of albumin and unfortunately the diazo-reaction which is so constant in typhoid fever, is also met with in general tuberculosis" (p. 219). "Typhoid fever has been mistaken for appendicitis. I was told of a case recently, in one of the large hospitals of this country, in which the fever and the presence of a tender induration in the right iliac fossa seemed to indicate appendix disease so clearly that an operation was performed, but the induration was found to be the swollen ileum and adjacent glands. In a person who has had a previous appendicitis the diagnosis might be extremely difficult, as in a case mentioned by Da Costa. Late in the convalescence of typhoid fever the symptoms of appendicitis may develop, due to the perforation of an unhealed ulcer" (p. 440).

These extracts from Osler show us that even a master may in some cases be unable to make the diagnosis of typhoid fever, except by autopsy. In this connection it might be said that a custom of holding more frequent postmortem examinations would ele-

vate the practice of medicine in any community. How many atypical cases of typhoid must run their courses under other names and even end unrecognized in death!

The means of diagnosis within the reach of the general practitioner, today, are the clinical and the laboratory methods. With the clinical we are all familiar, but the other methods have developed so rapidly, and are surrounded with so much technicality that the busy and over-worked doctor has not always taken the time to estimate them at their true value.

Much has been expected from bacteriologic examination. When any disease is proven to be caused by a particular micro-organism the problem of diagnosis would seem to be greatly simplified. The detection of the specific germ would appear to be an early and certain means of diagnosis. This is pre-eminently true of tuberculosis and diphtheria, but it is not true of typhoid fever. Yet it is sixteen years since Eberth and Koch discovered and demonstrated the etiologic relations of the typhoid bacillus—years which have formed a period of astonishing activity in bacteriologic research, so that today the technique of experimental bacteriology with its test tubes and cotton plugs, its culture media and thermostats, its guinea pigs, stains and microscopes, has become a familiar equipment in practical medicine. Nevertheless, the identification of Eberth's bacillus is too lengthy, too difficult, and too uncertain to compete with the clinical means at our disposal.

However, two methods deserve to be mentioned, namely, that of Elsner¹ and that of Hiss². The principle of Elsner's is that of almost every method yet proposed for the isolation of the typhoid bacilli. It is to add to a culture medium some substance which will prevent the growth of other bacteria without inhibiting the growth of Eberth's germ. The method of Hiss is based upon the characteristic spread of motile bacilli when grown upon acid glucose-gelatin agar kept semi-liquid at 37 degrees. Either of these methods requires two days for completion, and is too expensive to be used with any but wealthy patients, or under the auspices of a liberal board of health. As a matter of fact, it is now two years since Elsner published his method, yet we hear of no one using it in the diagnosis of typhoid fever. Within five weeks, however, the New York City Board has issued a circular announcing the new method of Dr. Hiss, its assistant bacteriologist, by which typhoid bacilli may be detected in the feces and urine of typhoid fever patients. It reads in part as follows: "The Health Department desires to thoroughly test this method and is prepared to undertake these examinations if proper specimens are furnished. The experience thus far obtained seems to indicate that the bacilli may be obtained from about 50 per cent. of all cases on the first examination and from about 90 per cent. after repeated examinations. The Health Board hopes that these examinations will prove of value not only for diagnostic purposes but also in solving sanitary questions relating to the presence in, and the time of disappearance of the bacilli from the stools during convalescence."

A prediction may be ventured that this method, like that of Elsner, will prove a failure in the prac-

tical diagnosis of typhoid fever. Eberth's bacilli may not appear in the stools until the tenth day or later. These facts are commented upon by Osler in his second edition. In fatal cases, even cultures from the small intestines obtained postmortem may not show the bacilli. But in the walls of the intestines, in Peyer's patches, in the ulcers, in the mesenteric glands, spleen and liver, the bacilli occur in large numbers and usually in pure culture. These facts explain the strictly limited success of the best antiseptic and eliminative forms of treatment, even including that of Dr. Woodbridge.

The obstacles to the early bacteriologic diagnosis of typhoid fever appear insurmountable. Have we then no early sign of the disease? Fourteen years ago Ehrlich tried to answer this question by an examination of the urine. He discovered the well known diazo-reaction. This valuable test has been strangely neglected by the profession as a body, and strangely misstated in some of the books, notably in the great work of Von Jaksch, in German, and in the "Medical Diagnosis" of Musser, in English. Osler, however, gives it correctly. The pink color of the foam is the distinctive feature of the diazo-reaction. It is present in nearly every case of typhoid and often by the fifth or sixth day. It usually disappears before convalescence begins, and varies in intensity with the severity of the case; hence it is a sign in prognosis. Unfortunately the diazo-reaction may occasionally be present in tuberculosis, in pneumonia and in septicemia.

Up to this point we have found no single sign or symptom, or combination of signs and symptoms which are invariably and exclusively present in typhoid fever. Our clinical anchors are the continued pyrexia, the diarrhea, the dicrotic pulse, the enlarged spleen, the roseolar eruptions and the lapse of time. The diazo-reaction gives additional security. If only these symptoms were all present in all cases we would not in years past have had to wait so often for the lapse of time to clear up the clinical picture, or finally to compromise on such a diagnosis as typho-malaria, pleuro-typhoid or typho-pneumonia. We may say that the clinical symptoms alone are usually insufficient to give us a positive diagnosis at an early stage in the disease, and moreover, are often insufficient to give a diagnosis at any stage. Even the best diagnosticians teach us how often a postmortem examination will reveal an unsuspected typhoid ulceration of the bowel.

The last eighteen months have, however, placed the diagnosis of typhoid fever upon a new foundation. Now we can detect typhoid at an early stage more rapidly and with more certainty than is the case with any other infectious fever. Still more suprising than this is the fact that we can tell whether the patient has had typhoid fever, months and sometimes years after recovery. It is done by the examination of a drop of the patient's blood dried upon a piece of paper. A drop of blood thus dried could be sent across the Atlantic and examined weeks afterward in Europe with the same precision that it could at the bedside of the patient. This is the serum-diagnosis of typhoid fever, which already, like the diphtheria antitoxin and the X-ray, has become an old story to the medical public. But since it is an old story some of you may have forgotten it, and I will risk a repetition of well-known facts.

The serum-diagnosis is based upon the discovery.

¹ For the practical details of this method see Crane, "Bacteriological Diagnosis of Infectious Diseases."—Supplement to the Report of the Michigan State Board of Health for the year 1896, No. 463, p. 111.

² For a complete account of Hiss's method see Hiss, "On a method of Isolating and Identifying Bacillus Typhosus."—Journal of Experimental Medicine, 1897, Vol. 2, No. 6.

by Pfeiffer of Berlin, of bactericidal substances in the blood of typhoid fever patients. He found, when the serum of such blood was mixed with an active bouillon culture of Eberth's bacillus in a test tube, that after a few hours in an incubator the bacilli were agglutinated in masses and had settled to the bottom of the tube, leaving the upper part of the bouillon clear. His original method, which required a considerable quantity of pure, sterile serum, was complicated and difficult. Widal of Paris greatly simplified the process by mixing a drop of the bouillon culture of the typhoid bacilli with a drop only, of the fresh blood serum and observing the reaction under the microscope. The active movements of the bacilli were arrested and the bodies of the germs became adherent, forming clumps which are characteristic of this reaction. Further investigation by Widal and Sicard showed that the drying of the serum did not destroy its bactericidal properties. It remained for Johnson, working independently of Widal, to demonstrate that "the fluid obtained by moistening a dried blood-drop gives the reaction in a prompt and satisfactory manner, even after it had been dried for several days." This modification brings this valuable test within the sphere of practical medicine and of municipal boards of health.

The microscopic examination of the hanging-drop preparation of Eberth's bacilli leads one to wonder why it is, that in a case of typhoid fever the patient's blood and every organ in his body are not swarming with these active, squirming, whirling, shooting germs: but when once the typhoid reaction is observed, when the active germs become quiet, when their dead and dying bodies agglutinate in clumps as though they had become partially dissolved and sticky, then we see that the patient's blood has developed a poison to these germs—a bactericidal substance—without which every case of typhoid probably would come to a fatal termination.

So remarkable a reaction speedily became the subject of very numerous experiments. It was found that, aside from blood, the reaction could be obtained in typhoid cases from blister serum, from pericardial, pleural, peritoneal and joint serum, from milk, from pus and from tears. The reaction is feeble in the juices of the spleen, kidneys and liver, while the sweat, saliva, and gastric juice are without the power. Practically we may use fresh blood, dried blood, and blister serum.

A pure culture of the typhoid bacilli is an unequalled necessity. It may be either a bouillon or an agar culture, and the bacilli may be virulent, attenuated or dead, and still give the reaction. If a dried drop of blood is dissolved in a drop of water, or if the undiluted serum is used, a fresh culture may give the reaction, occasionally, when the subject is healthy or has some disease other than typhoid. The reaction is quantitative rather than qualitative. It was found advisable, therefore, to use an attenuated culture, which is less sensitive, or else to dilute the blood or serum solution. Johnson's method is to use an attenuated culture and the dried blood without a definite dilution. He claims to thus practically eliminate the margin of error. The New York Board of Health uses a very active, virulent culture and blister serum in the dilution of one in ten. They claim reliable results in 90 per cent. of cases. As a summary of the many careful experiments, we may say that with a dilution of the serum, one in ten, or with a properly attenuated culture, and

a time limit of thirty minutes, the serum diagnosis of typhoid fever is as reliable as the bacteriologic diagnosis of tuberculosis and diphtheria.

Certain rare cases which, clinically, are typhoid fever, fail to give the serum-action with Eberth's bacilli. A number of observers, Johnson in particular, have found that the blood of such cases will, as a rule, react with the colon bacilli, thus indicating a colon instead of a typhoid infection. Johnson also found that a certain proportion of cases would give a positive reaction with either germ, thus indicating what would seem to be a double infection. Under these circumstances it seems wise in every case to examine the serum-reaction to the colon as well as to the typhoid germ.

The serum-reaction in cholera and certain other diseases is interesting, but has no practical connection with the diagnosis of typhoid fever. The greatest margin for error in the use of the serum-reaction lies in the fact that the blood may retain the power to react months and sometimes years after recovery. Thus it is necessary to exclude a previous attack of typhoid, and this may be difficult since any patient is likely to have had a mild or unrecognized attack.

In the very small proportion of cases where the clinical symptoms, the uranalysis, and the serum-reaction still fail to give us a positive diagnosis, we have additional means of very great value. If the decision lies between typhoid and malaria, an examination of the blood in cover-slip preparations will show us the presence or absence of the plasmodium malarie. If the balance rests between typhoid and any form of septic fever, cover-glass preparations of the blood, or better, the hemocytometer, will show us the presence or absence of an inflammatory leucocytosis. If the diagnosis is between typhoid and general tuberculosis, an examination of the sputum will sometimes, though far too seldom, give us the positive sign. But with these various means at the command of the profession, in addition to the clinical course and history of the case, it would seem no longer necessary for any case of continued fever to come to the postmortem table for a diagnosis.

To settle the diagnosis does not end the labors of the diagnostician in a case of typhoid fever. The case must be watched for complications. Pneumonia, pleurisy, pericarditis, meningitis, nephritis; the formation of pus in the middle ear, or in the spleen, liver, or brain; perforation, hemorrhage and peritonitis, are all to be dreaded by the attending physician. The sacred precinct of the clinician is even here invaded by the laboratory method. The uranalysis has long been a routine examination during the latter half of a case. Of greater importance is a routine examination of the blood. A leucocytosis means a complication. It may be an on-coming pneumonia or a meningitis or a purulent inflammation anywhere in the body. The latter, especially if it be a deep seated abscess, may be otherwise unrecognizable. However, it should be said that nowhere does careful clinical observation count for so much as during the course of typhoid fever in the presence of complications. Laboratory methods are strictly subordinate, and the old time general practitioner is a supreme necessity.

In conclusion, we may say that the diagnosis of typhoid fever may at times tax the utmost resources of the physician, and yet in no disease are the diagnostic resources so varied and so abundant. The clinician, the pathologist, the chemist, the hematologist

and the bacteriologist have been laid under tribute. And, as the product of their labors and genius, we have some of the most remarkable methods that have ever been applied to the study of disease.

REPORT OF A FEW CASES OF APPENDICITIS.

Read before the Camden City Medical Society, Nov. 3, 1897.

BY O. W. BRAYMER, M.D., PH.D.

CAMDEN, N. J.

I shall only report the histories of a few cases that have recently come under my care and not undertake to give an extensive digest of the history of appendicitis and its treatment.

Case 1.—T. R., male, aged 17 years, a farm hand, had been taken at about 8 A.M. with severe cramp-like pains in the abdomen, on the right side, low down, two days before coming to the Cooper Hospital. On the day I first saw him he was suffering great pain in the right iliac region. There was some distention of the abdomen, a history of constipation, a tendency to lie with the right thigh flexed on the abdomen, marked tenderness over the region of the appendix, together with tension of the abdominal muscles of the right side, and a mass could be outlined beneath the muscular wall in this region. There was some rise of temperature and a look of intense suffering on the patient's countenance. It was decided that the case was one of appendicitis and that operation should be done at once. This had every appearance of being a case of so-called fulminating appendicitis. I operated in the afternoon of the same day that the patient was admitted and as soon as the incision was made over the region of the appendix and the cavity of the peritoneum opened there was present a fecal odor. The appendix was found to be gangrenous, firmly adherent to the under surface of the cecum and contained several coproliths. After carefully breaking up the adhesions the appendix was amputated and the stump inverted into the bowel. The wound in the cecum was closed by a double row of fine silk sutures; the darkened spots on the bowel where the appendix had adhered, were carefully cleansed and nothing more done with them, as the discoloration seemed to be only superficial. I did what I will never do again in such a case, viz.: irrigated the cavity with 1 to 10,000 bichlorid solution and followed this with distilled water. I am now of the opinion that normal saline solution is one of the best fluids to irrigate the cavity with, following such cases. The wound in the abdominal wall was closed by one layer of sutures and a space left for a drain of iodoform gauze.

This patient suffered great pain for many days after the operation and had considerable difficulty in getting his bowels to move, notwithstanding he had taken small doses of calomel from the first, followed by the salines. There was very little discharge of pus from the wound, and after about the usual length of time, where drainage is used, the opening closed. The patient entered the hospital June 23 and was up and around his room July 13, but still complained of some pain in the region of the pubes. He was allowed to go home about one week later, and at that time was in very good condition. He was sent back to the hospital in a few weeks, suffering with intestinal obstruction, having eaten a large quantity of summer squash.

An operation by one of my colleagues revealed a constricted strangulated bowel, with much gangrene, and through the softened tissues a vast number of squash seeds were pointing in various directions. The patient died. The obstruction which caused his death was partially due to the adhesions which had formed during the attack of appendicitis, yet the final result might perhaps have been avoided, had the patient been more careful of his diet.

Case 2.—A. B., male, aged 43 years, applied to me in March to get relief from an attack of severe abdominal pain and vomiting. He stated that he had been sick about three days, with coryza and la grippe. I found the man in a state of collapse, with general abdominal pain and vomiting. He was given morphin with atropin and strychnin hypodermatically and after about two hours was left in a fairly comfortable condition. Divided doses of calomel were given to clean out the intestinal tract and gradually the abdominal pain settled down to a point of greatest tenderness over the region of the appendix. There was a slight rise of temperature and some chilly sensations. The calomel moved the bowels satisfactorily, but there gradually developed an area of dulness in the right iliac

region. There was a mass in the region of the appendix. He was removed to the hospital and was operated on at 9:30 P.M., March 18, 1897.

An incision over the prominent part of the swelling revealed about eight ounces of pus, which was evacuated and the cavity irrigated with a warm saline solution. A portion of omental tissue had been walled off by the pus pocket and, to avoid infection of the general peritoneal cavity, this portion of the omentum was ligated and removed. The wound in the peritoneum was closed with catgut, the muscular walls with kangaroo tendon and the skin with silkworm gut sutures, leaving an opening for drainage, the drain being composed of a small strip of iodoform gauze. This man had an uneventful recovery and three weeks after the operation was out and soon after resumed his business.

Case 3.—W. W., male, aged 21 years, came to the hospital April 12, 1897, with the following history: About two months previously he began to have attacks of severe abdominal pain, especially around the umbilicus and in the right iliac fossa, which pain had continued with more or less severity ever since. The bowels had been opened once or twice each day and there had been no nausea.

Examination showed great tenderness about the umbilicus and especially over McBurney's point, and the whole right side was tense and rigid. The patient when lying down kept the thigh flexed on the abdomen. No induration or fluctuation could be detected. The patient was told that he had chronic appendicitis and he decided to have the organ removed.

I made the usual incision through the abdominal walls, and found a thick, stiff appendix, pointing toward the umbilicus, somewhat adherent at the distal extremity and containing some fecal matter. The appendix was amputated close to the cecum. The stump was inverted into the cecum and the wound in the bowel closed by means of the Lembert suture, using two rows of sutures, made of number twelve black silk. The peritoneum, muscles and fascia were closed with kangaroo tendon, interrupted sutures, and the skin by silkworm gut. The patient had an uneventful recovery and was discharged cured May 4, 1897.

Case 4.—C. K., male, aged 19 years, came to the Cooper Hospital May 5, 1897, to obtain relief from excruciating pain in the abdomen, centering in the region of the appendix. This pain had been so severe during the past few days that it debarred him from any labor. Four years ago and again two months ago there had been similar attacks, but less severe. This attack began May 3, at 10 A.M., with sharp pains in the right inguinal region. There was no diarrhea or vomiting until after taking some soup the day before entering the hospital. Examination showed a tense abdomen, right thigh flexed when patient reclined, anxious countenance, tenderness in the right iliac region and a slight rise of temperature.

I operated upon him May 6, 1897. The appendix was found to have an adherent bulbous distal extremity; the adhesions were carefully broken up and the organ brought into view. The appendix was amputated near its colonic attachment, the stump was invaginated and the wound in the cecum closed with two rows of fine silk sutures, the peritoneum with a row of fine kangaroo tendon sutures and the muscles, fascia and aponeuroses were closed in a like manner. The skin was closed by a continuous intercutaneous suture, and the wound was dressed absolutely dry. There was some extravasation of blood under the skin, which on May 12 was discharged through the center of the opening. This discharge had a bad odor and at first was supposed to be fecal, but as no opening could be found through the muscular tissues, and as no further symptoms pointing to a fistula made their appearance, it was decided that the odor was due to the decomposition of the serum which had accumulated beneath the skin. The wound was cleansed and brought together by means of three silkworm gut sutures and recovery was uneventful. The patient was discharged cured June 4, 1897.

Case 5.—J. O., male, aged 15 years, came under my care as a private patient May 13, 1897, suffering from the ordinary symptoms of an acute attack of appendicitis. He was treated by absolute rest in bed, calomel in divided doses, together with salines and a liquid diet.

May 20 there was great tenderness in the right iliac fossa, temperature of 102.5 F., rigidity of muscles of right side of abdominal wall, a tendency to keep the right thigh flexed on the abdomen and a circumscribed swelling in the region of the appendix. I operated at 5:15 P.M. About eight ounces of very offensive curdy pus was liberated and the cavity irrigated with a saline solution. The incision was closed by means of five interrupted silkworm gut sutures, leaving room for a small iodoform gauze drain which was inserted. The patient was discharged June 3, having made an uneventful recovery.

Case 6.—A. J. S., aged 30 years, came under my care at about the same time as did Case 5. The two cases had about the same symptoms, tenderness and temperatures, and both were treated similarly up to the time that Case 5 required operative measures. This man, however, made a good recovery in about three weeks without any operation and has had no return of the symptoms, with the exception of slight pain, at times, in the region of the appendix, but not severe enough to call for further interference.

At this writing all of the above patients, with the exception of Case 1, are well and attending to their usual duties.

In my own practice and in consultation with my colleagues I have, in the past year and a half, seen about twenty cases of appendicitis of almost every degree of severity, and I have become thoroughly convinced that, as a rule, the surgeon is not called early enough in the development of the disease to get the best result.

In treating chronic recurrent cases, unless they progress badly, it is best to wait until there is a lull between the attacks, for this is the most favorable time for operation.

If we are convinced that an abscess is forming we should wait, if the case will allow, until the abscess wall is strong enough to withstand surgical interference.

In abscess cases I would never hunt for the appendix if it is not present in the pus cavity.

I believe the best method of removing the appendix is to cut it off close to the cecum and treat the wound thus formed as you would any other small wound in the intestine.

And finally, in my opinion, it is bad practice to apply blisters and like remedies over the region of the appendix, when treating the disease, because, if operative measures are subsequently adopted, there will be more probability of suppuration and sloughing in the wound.

SAVE THE PIECES.

Read before the Fox River Valley Medical Society April 27, 1897.

BY J. R. BARNETT, M.D.

NEENAH, WIS.

It is not long that "conservative medicine" and "conservative surgery" have been familiar terms to our ears; and yet by reason of their repetition it seems long. They would have sounded strangely in the mouth of a Watson or Erichsen, and were tentatively and diffidently spoken by a Flint and a Gross.

Every day has its surgical record which reads as if the word conservative had not been incorporated into the language of our art: and as if surgery meant only amputation, mutilation, disfigurement, and as if her chosen collaborer were that carpenter of prothetic art, the wooden-leg maker. If one had the power to glean the facts and give a clinical report of the needless mutilations of yesterday, done under the stress of supposed necessity, of fingers and toes, hands and feet, arms and legs, amputated because their salvation was doubtful or deemed impossible, it would be a ghastly record. Preservative surgery is a term more in harmony with our conception of a surgeon as one whose art is invoked to save, first the man, and next, as much of the man as possible. Our old student admiration for the surgeon who could complete a major amputation in four minutes by the watch, and triumphantly exhibit three-fourths of a man as secured to life, if laudable pus but crowned his skillful work, is now quite misplaced. The compound fracture and the lacerated tissues that justified it then would offer no

defense now. We have to answer to our conscience, the question, can the limb be saved, even at a little greater risk to life, and at the added cost of much longer, pains-taking and unattractive care in the after-treatment? We have even to face the clamor, grown popular as well as professional, for an aseptic operation that shall make even laudable pus both unlaudable and reprehensible, and that shall make the final treatment of the wound a matter of one or two dressings. The surgeon delights in such an operation, and the people look upon anything less as evidence of unskilful work. Nevertheless, the present requirements of our art are such that we must face the charge of reactionary and retrogressive tendencies, since preservative surgery means something of a return to the patchwork of olden times, and something of a flouting of that potent organism, not then recognized in high scientific circles, the pus microbe. If we are to save the pieces, we must often save them in company with several busy colonies of that same microbe, which not all the antiseptic scrubbing and irrigations will with certainty avail to wash away or kill. A hand mangled on the dead-wood, or crushed in the dirt of the street, is the certain host of innumerable germs; and the temptation to dispose of both host and guest, once for all, by a few touches of the knife and saw, is a deadly one; but it is a temptation to be resisted so long as whole blood vessels and nerves traverse any portion of the mangled member. Every finger and part of a finger in which life can be kept should be spared, even if the bones are fractured, and the fractures are compound. Is its integument partly gone? Patch it up.

Is a partial excision necessary, with any part of the saved member of doubtful vitality? Patch up an excess of integument at the amputated part to hold in reserve for the possible needs of repair later on. If such repair is needed you will bless your provident forethought; if it is not needed the redundant integument will atrophy and disappear, if not too great, or it can be easily trimmed away.

Frost bitten members should be put in a protective dressing until nature points out the utmost limit of vitality; and the saw or bone forceps should be about the only instrument needed to complete the amputation; for nature has shaped a bloodless flap, which will fall naturally enough over the end of the severed bone.

Burns of the extremities, involving the deeper tissues, should be treated in the same way. The preliminary waiting will be safer, for the destructive agent has sterilized the part with the utmost thoroughness.

To discuss conservative operations with reference to prothetic aid later on, would need both more time and an abler essayist. The question has been much considered from both sides, and both sides have seemingly strong arguments.

Permit me to outline a few cases:

Case 1.—A workman in a planing mill had the back of his hand so lacerated by a saw that the integument was literally in strips. Some of the extensor tendons were shredded up and some of the phalangeal bones uncovered, and in a few places sawn through. Every finger, including the thumb, had at least one joint opened up and more or less injured.

The shredded, soft tissues were trimmed away, the multiple lacerations carefully sutured, and a protective dressing and splint applied. A thoroughly useful hand was saved, and one not greatly impaired in its necessary movements.

Case 2.—A man aged 60 years, froze all the fingers of one hand. When he consulted me, a few days later, three of the fingers were swollen and discolored their entire length. Fortunately he had done them up at the outset in antiseptic cotton, so that they were in good condition for preservation until a limitation of vitality could surely be made out. He lived at a distance, and various delays occurred, so that amputation was not performed until a month later, when I found the fingers, nearly to the bases of the middle phalanges, completely mummified. The living integument was pushed up a little, the bones severed with forceps, and the rather serrated flaps allowed to fall into position, no suture being used. The stumps were not handsome at the time, but in a few weeks they looked as well as if fashioned with the most fastidious care, and each of them possessed one more joint than it would have had had the amputation been primary.

Case 3.—A brakeman sustained a crushing injury of the hand while coupling. The third and fourth fingers and the ulnar side of the hand were completely pulped and devitalized. There were compound fractures of all remaining phalanges excepting the thumb, the soft tissues being frightfully lacerated, but offering a promise of preservable vitality. Excision was done through the crushed metacarpal bones, patches of integument from the sacrificed finger being pieced together to close the wound and afford a surplus for later repairs should sloughing occur. Lacerations were sutured and ample drainage provided, and the man was sent to his home, where the most difficult part of the treatment fell to Dr. Bishop, the company's surgeon. I heard two weeks ago that the two fingers had been preserved, and the patient thus left with a comparatively useful hand.

Case 4.—February 9, a man of about 60 years of age, was caught by a moving train in such a manner that the integument was torn wholly loose from one foot, the accompanying laceration reaching from the base of the great toe, along the inner border of the foot, across the ankle and along the outer border, to the metacarpal bone of the little toe, which had sustained a compound fracture near the head. The toe was shucked out of its integument, and so was removed, with its metacarpal fragment, the skin being patched up for later repair. There was also a compound fracture of the tibia just above the malleolus, not to mention an intercondyloid fracture of the humerus of the same side, a fracture of a rib on the opposite side, and several lacerated wounds of the scalp. The skin of the foot was completely detached and crushed through at two or three points, so that the finger could be passed about underneath it, while most of the foot could be laid bare. The dirt upon, and underneath, and all about, was appalling; and much labor was spent in cleansing what may, with double aptness, be called "the field." It took more than two hours to do this and properly suture, drain and dress the foot, putting it in a fixation splint. No anesthetic was needed, as, partly from the traumatic anesthesia, partly from the head injuries, or possibly from the "drop too much," which is the usual incident in such cases, the patient felt but little pain. No part of that elaborate patch-work was saved except a fragment from the little toe and from near the base of the great toe. From a line surrounding the foot at these points to another surrounding the ankle, every vestige of that integument with its fascia melted utterly away. Most of the flexor brevis digitorum shared in the destruction, together with much of the tendo Achillis at its insertion, while the posterior surface of the os calcis became carious and had to be cut and scraped away. The wound became infected from the first, mainly by the bacillus pyocyaneus; and with the infection and the devitalization of patches of unknown depth, here and there, it took six weeks to get the field ready for grafting; the compound fracture of the tibia meantime sharing for a few days in the suppurative process, though afterward uniting rapidly. The Thiersch method of skin grafting was employed, upon the sole first, to stop cicatricial contraction as promptly as possible. The surface was most thoroughly curetted and completely covered by grafts removed from thigh. These were covered in by the usual strips of rubber tissue; a copious dressing of iodoform and sterile gauze saturated with normal saline solution was applied; over this a sheet of oiled silk, and over all a free covering of sublimate cotton. When this was removed, the fourth day afterward, every graft was alive, and only one necrosed a few days later on, when the sole of the foot was

practically closed in. Eight days after the first grafting the dorsum of the foot was similarly covered by grafts taken from the other thigh, every one of which survived, although they were not placed everywhere in contact. Now, after two weeks, the only open spot is where the deeper mischief to the os calcis and tendo Achillis was done. This is closing by granulation, although it may need another curetting.

One can not say how soon the foot can be useful for all service. Probably, owing to the thinness of the new covering and the absence of subcutaneous fat, it will take many weeks, or perhaps months, of careful use with a deeply padded shoe; but that in the long run the superior usefulness of the natural member over a wooden one will fully reward all parties concerned for the tedious and unattractive work bestowed upon it, admits, I think, of no doubt whatever.

AN UNUSUAL EXPERIENCE IN DIPHTHERITIC INFECTION.

Read at the Thirteenth Annual Meeting of the Second District Branch of the New York State Medical Association.

BY E. D. FERGUSON, M.D.

TROY, N. Y.

March 15, 1897, I was requested by Dr. M. B. Hut-ton of Valley Falls, N. Y., to visit a family in which four members had been stricken with illness in an unusual and very serious manner.

The family consisted of the father and mother, a daughter, two sons, and a brother of the father. The daughter had been away from home, teaching school, until three or four days prior to my visit.

The cases were as follows, viz:

C. M., a boy, aged 14, became ill March 4 with the ordinary signs and symptoms of lobar pneumonia. The local physical signs corresponded to the ordinary course of the pulmonic disorder, and March 11 the lung had so far cleared as to show that some element other than ordinary pneumonia existed, for instead of an improvement in the general condition, the symptoms became progressively worse, and the patient died March 13. No complaint had been made of discomfort in the throat, and no evidence of trouble was present there, until it was too late to examine. This patient died two days before my visit.

I. M., a boy, aged 11, became ill March 9, presenting, in the same manner as his brother, the usual signs and symptoms of lobar pneumonia. A favorable course was pursued until March 14, when a membranous exudate was discovered in the throat, and death occurred March 16.

E. M., aged 62, the father of these boys, was taken ill March 11. He, also, presented all the physical signs and the symptoms of lobar pneumonia, but March 14 the throat showed an exudate and death resulted March 16.

J. M., aged 70, a brother of E. M., became ill March 12, but refused to go to bed until the following day. In his case all the classical signs of lobar pneumonia were present, but March 14 the throat trouble had developed, and death supervened on the 16th.

Of these patients, one died two days before and three were alive at the time of my visit, but they died during the following day.

The lad, I. M., was in a profoundly toxic condition, and in so profound a stupor as not to realize anything concerning his surroundings, in fact he was evidently moribund. The other two patients were fairly comfortable, having passed the stage of pain due to the pneumonitis and its associated pleurisy, the mind of each was clear, the pulse was of fair strength and not greatly accelerated, and the temperature was only slightly raised.

The pneumonitis in each and all the cases had been limited to a single lower lobe. The physical signs in the lad taken ill six days before my visit, indicated that resolution was nearly complete: in the case taken ill four days before my visit resolution had made pos-

itive progress, while in the one taken ill three days before, resolution had not begun. It seemed reasonable to hope that recovery would occur in the last two cases, but soon after my visit stupor and exhaustion developed so rapidly that they died during the following day. The exudate in each of the three cases which I saw, was quite extensively spread over the pharynx, involving the palate and uvula, and extending at some points below the parts visible on inspection by the aid of a tongue depressor. This false membrane was similar to the ordinary exudate in diphtheria, though the color was possibly a shade darker or more "muddy" than is usual.

Attention was given to the throats of the mother of the lads and her sister, who had been for several days in the house, with the result of finding redness in the pharynx of the former and a thin ash-colored exudate in the latter. Both had a slight rise of temperature, and it was deemed prudent to inject the antitoxin of diphtheria. They had no subsequent trouble.

The daughter, who had recently returned home, did not become ill, nor did any of the neighbors who casually visited the house, contract the disease. Of the four who died, not one had been away from home for a considerable period of time, nor had there been a case of diphtheria, aside from the one to be mentioned later, within a wide region thereabout, or within at least a year's time. Careful and thorough enquiry failed to disclose a source of contagion whence the disease could have originated.

The fact that lobular but not lobar pneumonitis is often due to diphtheria, and the additional fact that each of these cases began as a lobar pneumonia, that the pneumonic element of the cases made favorable progress in each instance, and that death seemed to result from some associated condition, made the problem very strange and puzzling. As no postmortem examination was had, the character of the lung trouble must be left to inference, but some of the pharyngeal exudate was subjected to bacteriologic examination. Upon staining portions of the exudate taken from the throats, the micro-organisms present showed the morphology and reaction to coloring agents that would belong to a pure culture of the Klebs-Loeffler bacillus. Several cultures were made and tests carried through all the media necessary to justify the conclusion that the throat trouble was true diphtheria.

On my return from visiting these patients, I saw a case in Valley Falls which was similar to these, except in the result. It was that of a young man who had been ill for a sufficient length of time to be in a convalescent state at the time of my visit, although some exudate remained in his throat which presented the same appearance and gave the same microscopic results as in the other cases. He also had the initial pneumonia.

Having thus settled that the disease and cause of death in these cases, aside from the pulmonary element, was diphtheria, the source of infection became the subject of enquiry. The development of the disease in the four male members of the family within so brief a period of time, would justify the idea that there may have been a common exposure, though the first case may have been the source of infection for the others.

It was found that, just before the development of the first case, the four had spent some time in the cellar "sprouting potatoes." This cellar had foul air due to the presence of decaying vegetable matter. There was

also in the cellar an unused well. In view of the more recent views concerning the sources of infection in diphtheria, it did not seem probable that the cause would be found there, and a bacteriologic investigation of the cellar did not seem practicable. That the pneumonia may have originated there is not impossible or even improbable, but there did not seem to be any practicable method by which such a problem could be settled.

The difficulties which accompany such bacteriologic investigations are exemplified in the following search for the source of the diphtheria. By chance it was learned that a well existed some distance back of the house, and not far from the barn. The water of this well had been so offensive that it had been "pumped out" several times during the winter, but without removing the offensive odor. In spite of the offensiveness of this water, it was known that three of the patients had drunk from the well, and probably the fourth had done the same. Though hardly expecting to find the source of infection in the well, some of the water was taken by Dr. Hutton in a clean bottle and brought to my office for examination. The offensive odor of the water was manifest when the bottle was opened in my office, though the water was clear to the eye.

Plate cultures were made from the sedimented portions taken from a centrifuge tube, with the following results: They showed the morphology, and staining reactions of the Klebs-Loeffler bacillus, and had investigation ended with the ordinary tests made to detect and differentiate the diphtheria bacillus in throat trouble an error would have resulted, for the conclusion would have been reached that the bacilli found were the cause of the diphtheria. Some stab cultures were made from the plate cultures and the material was carried through the various tests to settle the question. Even with this care, at first it was probable that we were dealing with the diphtheria germ, but the tests, which extended over several weeks of time, finally showed that this bacillus was one of the numerous water-bacilli which do not liquefy gelatin. We were thus left without an explanation of the origin of these cases. That in some way there had been an exposure to the special cause of diphtheria, and an incident exposure to the pneumococcus, is a reasonable conclusion, but the source of each must remain unknown.

The conjunction of these two probably distinct diseases in each of the entire series of cases, renders the instance rare and interesting. While we can not affirm that the pneumonic trouble was distinct from the pharyngeal disease, still the clinical history and distinct limitation of the lung element to a single lower lobe in each case, would justify that inference.

COLOR PHOTOGRAPHY AS APPLIED TO DERMATOLOGY AND SYPHILOLOGY.

Presented to the Section on Cutaneous Medicine and Surgery at the Forty-Eighth Annual Meeting of the American Medical Association at Philadelphia, June 1-4, 1897.

BY W. S. GOTTHEIL, M.D.
NEW YORK, N. Y.

The correct picturing of the manifold lesions of the skin is a matter of interest to those engaged in the study of dermatology. It is important, first, to secure a permanent record of a rare dermal lesion. Only by plastic or pictorial representation can the evanescent

forms of skin disease be fixed and held; for a verbal description, no matter how exhaustive or how carefully made, is necessarily insufficient as regards form and distribution, and more especially as regards color; and second, the multiplication of such reproductions is of importance to us for the purposes of journal and book illustration.

For record or demonstration, models or casts in plaster, wax, or paper, are undoubtedly most satisfactory; for shape, location, color, all the factors necessary for diagnosis, with the exception of those perceptible to the touch, can be reproduced with an exactitude and a verisimilitude that leaves nothing to be desired. Unfortunately, however, this method of reproduction is tedious, dirty and troublesome; and a necessary factor for its successful execution is an amount of artistic discrimination, taste and skill, that is not in every one's possession. The time required for the preparation of models, and the expense involved therein, will continue, I think, to restrict their use and limit their production. Paintings in oil and in water colors are expensive luxuries when done with any finish and attention to minute detail; and the artist's individuality, the things he sees, or thinks he sees, the methods that he employs to depict these things, in other words the personal equation, is often painfully apparent. Photographic reproduction, while excellent for minute detail, necessarily neglects the very important element of color entirely. True color photography appears to be still far in the future, unless the recently loudly heralded process for that purpose that has come from Paris should prove to be more reliable than its predecessors.

Turning now to the production of illustrations in quantity, it is very apparent that a process that is to be practical, more especially as regards expense of production, must be one that can be accomplished wholly by mechanical means. The photo-mechanical processes and photogravure have been greatly developed in recent years, and the results obtained from them are in many respects admirable. But the same objection of the absence of color applies to them as to photography. The various processes of colored depiction, that I may group as the chromo-lithographic, have in some cases given good results; but there is in most of them a crudity and a grossness of coloring that render them diagrammatic rather than pictorial.

Some two years ago my attention was called to a process in which, by the conjoined use of the camera and the press, representations of objects in colors true to nature could be obtained and reproduced in unlimited quantities at a moderate cost. Printed by this so-called "three color process" I saw a number of copies of paintings, rugs and other flat objects that were surprisingly accurate in form and coloring. It had not up to that time been used on life subjects; but on inquiring into its method, I saw no reason, other than possible technical ones, why this should not be done. It seemed to me that, if this method could be successfully developed, it would be of value in various departments of medicine, and especially so in dermatology and syphilography. Photographs could be made by an ordinary operator, or by the physician himself, from life; and the negatives once successfully taken, reproduction to any extent could readily be done. I found that the cost of the method compared favorably with that of any of the other color methods, and not very unfavorably with that of plain black and white. The technique I found to be

apparently simple. Nevertheless, as might have been expected, I found difficulties enough therein, and to spare. The method is as yet imperfect, but I believe that it will be simplified and developed, and I call attention to it here for the purpose of recommending its trial to those who are in a position to do so.

The entire process may be divided into two parts, the first and essential one to be done by the photographer, and the second, the actual printing of the copies, being necessarily left in the hands of the skilled photo-mechanical printer. It is with the first that we are most nearly concerned, since the second can be done at any time, and in various ways. The apparatus required is the following:

1. *Camera and lens.* Of these little need be said. Any camera on a firm stand, and provided with three accurately fitting and exactly similar plate-holders will do. The main requirement for the portrait lens is rapidity of action, for reasons that will be apparent later on. An accurate time shutter is needed, since the cap can not be employed, as the front rim of the lens is occupied by the color screen holder. I employ a large portrait box, with a Zeiss portrait lens, and a Bausch and Lomb shutter.

2. *The color screens.* These are the most important parts of the apparatus, for the successful carrying out of the process depends entirely upon the accuracy of their color values. There are three of them, a blue, a green, and a red. Each one consists of two sheets of very thin and perfectly flat white glass sufficiently large to cover the entire front of the lens to be employed, and containing a thin layer of transparent pigment between them. It has been found impossible to obtain colored glass of the proper values and thinness, and the preparation of these screens is a matter of extreme nicety. Not only must the glass be without flaw, absolutely true, and of great thinness, but the pigment, which is dissolved in gelatine, must be spectroscopically correct; and the least impurity, dust or pigment granule, or air bubble, greatly impairs the value of the screen. Sets of them are sold by some of the makers of photographic plates; but I have found it impossible to obtain proper results from some of those in the market. The set that I now use were especially made for me by Mr. Ernest Edwards, of the New York Photogravure and Color Company, who has done much to develop the three color process. The screens are held in a frame that slides in a holder attached to the front rim of the lens, so that no light can reach it save what comes through the colored glass.

3. *Plates.* Iso-chromatic or ortho-chromatic plates, which give most nearly the true color value of objects are the only ones that can be employed; and of these the slowest that can be obtained are the best. I employ only the Cramer iso-chromatic slow plates. Ordinary plates are entirely useless in this process.

4. *The developer.* Any of the standard developers can be employed; but the yellow tints, that are so frequently gotten with pyro are objectionable, and it is not infrequently a source of failure in printing from the plates. I have found the amidol developer to be the best for this process.

The details of exposure are very simple. Three plates are exposed successively, one through each of the color screens. During the entire time of exposure including the time required for changing the plate holders and the color screens, and setting the shutter, the patient must keep entirely still. The slightest

movement on his part will cause the negatives not to register, as it is called; the three superimposed gelatin plates will not print over exactly the same lines, and the set is spoiled.

The method of procedure is as follows:

1. *Posing.* The part to be photographed, be it face, limb, or the entire body, should be lighted up as well as possible, but evenly, great care being taken to avoid as far as possible deep shadows and sharp contrasts. All the essential parts of the picture should be upon the same plane; for, as will be seen later on, those portions of the picture that are not in focus will not only be indistinct, as in ordinary black and white photography, but will be of wrong color also. This difficulty does not occur in copying pictures or flat objects, and pictures of perfect faithfulness can be obtained. It is inherent in life work, where it is impossible to have all points of the picture in focus at one and the same time.

The background should be of a neutral tint, not black or white, so that its exact color in the picture is a matter of no importance. Being necessarily out of focus, its color will inevitably be different from the reality.

2. *Color scheme.* A piece of paper striped with the three primary colors, must be so arranged as to appear on the negative, to inform the plate maker and printer as to which plate each one is, and to guide the latter in the exact superimposition of the plates.

3. *Exposure.* Here the main difficulty and the crux of the process is met with. Three plates are to be exposed at one sitting; the plate holder must be changed three times; and at each change the color screen must be moved, and the shutter set. Over and above this, the time of exposure is long: it takes many seconds for the light to act on the sensitive plates through the color screens. The exact time of exposure varies with a number of factors, and is a matter of nice judgment. The thickness of the color screens, the length of draw of the camera, the amount of the ever varying light, the color of the object to be photographed, all these must be taken into account in determining the length of time during which each individual plate must be exposed. This is long enough under the most favorable circumstances, and all attempts to diminish it materially have so far failed. Magazine cameras, arrangements by which one plate after the other is exposed inside the camera by mechanical means, and arrangements designed to facilitate the changing of the color screens have not proved to be of much practical value. The time occupied in these manipulations bore so small a proportion to the total time of exposure that it did not seem worth while to continue the experimentation in that direction. The slow plates and the screens necessitate the employment of the quickest possible lens; the diaphragm should be left wide open; and the process should only be undertaken at the middle hours of bright days, when the light is at its strongest.

I usually expose the plate through the blue screen first, then through the green, and last through the red. This is for the reason that the more rapid the action of the light upon the sensitive plate the greater the disturbing effect of slight movements on the patient's part will be; and though such movements are most likely to occur during the last and longest exposure, it will have less effect during the exposure through the red, the slowest of the screens.

The exact time of exposure for each plate is so

variable that no exact rules therefor can be laid down. In a general way I have found that the proportion between the quickest exposure, that through the blue screen, the medium one, through the green, and the slowest, through the red, to be as one, two and four. An average exposure under moderately favorable circumstances requires twenty seconds for the blue, forty seconds for the green, and eighty seconds for the red screen. In exceptional cases, with very good light and small camera draw, the time may be reduced to fifteen, thirty and sixty seconds. The reverse, however, is more frequently the case, and exposures of twenty-five, fifty and one hundred seconds must not infrequently be made. Allowing twenty seconds for the necessary changes in plate holders, screens and shutter, all of which with practice can be done with great rapidity, this means a total exposure of from 125 to 195 seconds, or from two minutes to a little over three. This might not have seemed considerable in the old daguerreotype times, but it is a very long sitting today, and difficult to obtain with our ignorant and often sickly and nervous patients. I have had failure after failure, amounting to many hundreds, simply from inability to secure the necessary quietude, in spite of all manner of mechanical devices to immobilize the patients.

4. *Development.* The plates are developed in the ordinary way, and to the usual degree. After fixing and clearing they do not differ materially in appearance from ordinary negatives for black and white printing. The pictures of the color schemes above mentioned will serve to differentiate the plates, and show the degree of correctness of the color values of the screens: in each negative of the three one color, and a different one will be cut out and be absolutely transparent. The printing value of the negatives depends almost entirely upon the sharp and complete cutting out of the colors.

The rest of the process belongs to the domain of the mechanical color printer. From each negative of a set a gelatin plate is made, and three printings, in yellow, red and blue ink are made to complete each picture. This is done on a hand press; but skilled labor of the highest kind is required, since the slightest inexactitude in the superposition of the successive printings gives a faulty impression. As a rule the yellow is printed first, then the blue and then the red. But this is not an invariable rule. Slight changes of tint can be obtained by varying the order of the printing, the color which is required to predominate being printed last. From the admixture of the colors in varying proportion, or rather, from the combination of the different layers of the semi-transparent colors, all the varying tints are obtained. There is probably no more difficult color to imitate than that of flesh, and no one in which there are more different tints, and the successful flesh color that can be attained shows the essential value of the process. Two colors, however, can not be perfectly attained, viz.: pure black and pure white. With all possible care in the selection of pigments, they can not be procured sufficiently pure to give these.

There are certain well-marked limitations to the use of the three color process, and in some cases it can not be used at all. First, we can not expect to obtain with it a sharpness of definition equal to that of plain black and white printing done from one plate. The mere fact that three printings are made from three different plates would prevent that. Second, the

prints of a series are not and can not be absolutely uniform; there are inevitably slight differences due to the varying amount of ink upon the rollers, and to the varying effect of the temperature and moisture of the atmosphere upon the gelatin plates. Both of these minor objections I hope to see removed in the future by the application of the process of stone.

Then again, not all portions of a larger picture from life can have true color values. This is perfectly possible in the reproduction of a flat object, as of a painting, the whole of which is upon one plane. In photographing from the living subject some parts of the actual picture, and all the background and accessories are necessarily out of focus. In plain black and white printing this simply means indistinctness of definition in the non-essential parts of the picture; a thing that we are accustomed to, and no longer notice. But in the color process the parts out of focus are not only indistinct, their color is not quite true to nature. This is a limitation inherent to the process, and is not of much importance from our point of view. Our object is attained if the affected skin and its lesions have the correct tint.

Finally, certain cases are entirely unsuited for the process. Children can not be so photographed, for they can not be kept still long enough; nor very old or nervous individuals for the same reason. Larger pictures of the integument of the trunk are frequently failures, on account of the inevitable lateral motion. But antero-posterior motion, to and from the camera, does no harm, and smaller sized pictures of the entire trunk can be taken with perfect success.

And now a final word as to its advantages and possible field. Larger pictures of the face, lower part of the trunk, and of the limbs, and smaller ones of larger areas of the body can be readily taken in appropriate subjects. For the reproduction on a large scale of paintings in water colors or in oils, or of casts, it is entirely suitable. It requires for its photographic part little more than the ordinary photographic apparatus, and ordinary photographic skill. So far as its cost is concerned, it is even for a single print much less than a properly colored drawing or a painting. A few dozen cost no more than one; and for larger quantities the expense compares favorably with that of the older mechanical color processes.

INEQUALITY OF THE PUPILS OBSERVED AT AN ALTITUDE OF TEN THOU. SAND TWO HUNDRED AND FIFTY FEET.

Read before the Colorado State Medical Society.

BY E. T. BOYD, M.D.

LEADVILLE, COLO.

The time when it was thought possible to foretell the character of insanity by noting which was the larger pupil has long since passed away. It is also my opinion that when the influence of great altitude upon the general economy shall be better understood, the time when we, as physicians, were inclined to regard inequality of the pupils as more than presumptive evidence of serious lesions, will have become ancient history.

My reasons for bringing this subject (anisocoria) to your notice are many, the main one being to impress upon you that there may be unequal dilatation of the pupils which is in no way indicative of the lesions to

which we are commonly in the habit of attributing it. So far as I can learn, but little has been written upon the subject, and that little deals with it as a symptomatic manifestation of graver troubles, such as tumor of the brain, glaucoma, and disease of the retina and optic nerve.

Inequality of the pupils may be observed in many and varied conditions. Traumatism of the globe may produce it; it is seen as a sequel of diphtheria, and may occur from peripheral irritation, for instance, ulcers on the septum of the nose, or from some intestinal trouble.

But it is not the purpose of this paper to discuss all the causes of, nor all conditions in which it may be found. I desire to treat of it as a peculiar abnormality frequently seen and in some way due to the environment of persons living at a great altitude.

Anisocoria may be seen in both male and female, children and adults, regardless of occupation or manner of living. A physician in whom I had discovered unilateral mydriasis had noticed the same thing in his three year old son. I have records of over one hundred cases observed in Leadville during the past year, and am sure that I could easily find as many more.

Believing inequality of the pupils as observed in Leadville to be wholly due to the altitude, I inferred that a like condition would be found in persons living in and about Cripple Creek and Victor. Through the kindness of Dr. Boyd of Victor, and some of his medical friends, I am enabled to say that it is so common that the doctor in writing me stated that it might be seen in one-third of the older residents—those having lived there from one to five years.

Fuchs says: "Inequality of the pupils is always a pathologic phenomenon." Noyes states: "Dilatation of one pupil of slight amount with preservation of its activity is sometimes seen as an unimportant affection which may continue for years. Its cause is unknown, but it is probably local to the iris." True, the cases to which I refer have not been under observation for sufficient length of time to enable me to thoroughly eliminate all possible connection with graver maladies. In progressive locomotor ataxia, anisocoria may appear several years before the disease is fully manifest. But, taking into consideration the comparative rarity of posterior spinal sclerosis (this, I believe, is more common at a great altitude than at sea level) and the marked frequency with which unequal dilatation of the pupils is seen in Leadville, together with the total absence of the Argyll Robertson or characteristic pupil of tabes: added to which we find the patella tendon reflex to be normal: all this disposes me to believe that there can be no connection between the cases referred to and the disease in question.

In regarding a case of unequal dilatation of the pupils, the first thing to do is to decide whether there is myosis in one eye, or mydriasis in the other. In other words, which, if either, is the normal pupil. In the following cases this has been done as nearly as may be, by noting carefully the reactions to the various stimuli, and by comparing them with apparently normal pupils observed under like circumstances and conditions. I think that there can be no doubt but that results warrant the statement that they are all cases in which unilateral mydriasis exists.

For the purpose of avoiding too frequent repetition, I will speak in a general way concerning features which in the main are common to all the cases

observed. From none could there be elicited aught but negative history, either immediate or remote. All of the subjects are in excellent health. The men are moderate drinkers and smokers; but few of them have had visual disturbance, and in these cases the trouble was due to some minor refractive error. Rarely in these cases have I found anisometropia which may occasionally be the cause of anisocoria. Pupils reacted consensually, also responded normally to light; convergence and accommodation in all cases except Nos. 6 and 9; the departure from normal in these cases consists in the peculiar reaction first described, I believe, by Gowers, as follows: "Immediately upon exposure to the light the pupils contract; light stimulus being continued, the abnormally dilated pupils rapidly regain their former size."

In all cases that I have had the opportunity of observing frequently, I find that there are times when the pupils are of equal size. The exacerbations can not be associated with excesses of any kind. In about one-half the cases seen the right pupil was the larger, while in the remainder the reverse obtained. The difference in size ranged from one-fourth to three-fourths times larger than the smaller pupil. Incidentally I may mention that I have seen the same condition of unequal dilatation in dogs. Paresis or paralysis of the fibers of the oculo-motor nerve supplying the sphincter of the iris, irritation of the cilio-spinal center of the cervical spinal cord or the cervical sympathetic supplying the radiating fibers of the iris will produce dilatation of the pupil. As long as the third nerve functions properly, presupposing the optic nerve and retina to be intact, the reaction to convergence and accommodation will be normal. The accommodation unimpaired, with normal reaction of the pupils to convergence and accommodation, I think it safe to conclude that the unilateral mydriasis is not associated with impaired function of the third nerve, hence we naturally look to the sympathetic system for the cause of the abnormality.

The idea is quite general that there is a condition of enervation in persons residing in Leadville or at a like altitude. Knowing of this impression, I have employed the best means at my command to learn the truth or falsity of it. I find that the physicians of that district, almost with one accord, believe that the conditions dependent upon altitude cause innervation rather than enervation. The laboring men interrogated upon the subject bear out this opinion. Fifty miners, taken at random, being asked as to their general feeling of well being and their ability to do work as compared with a lesser altitude, forty-five of them thought they could do the same amount of work with greater willingness and less fatigue after having accomplished it than at a lesser altitude, while five believed the reverse. It should be stated, however, that the five last mentioned experienced difficulty in breathing. Most people coming from sea level to an altitude of 10,250 feet, become exceedingly short of breath upon slight exertion, and may have tinnitus aurium and a feeling of giddiness, because they are accustomed to breathing a much denser atmosphere and their lungs are not equal to the task of obtaining the requisite amount of oxygen from the rarefied air, and for a time there is enervation. If the lungs are healthy, a residence in Leadville will soon bring about a compensatory increase of lung capacity. This, with increased circulation of the blood, enables one

to obtain all the oxygen required and he will no longer be handicapped by dyspnea. When the lungs and circulation shall have adjusted themselves to the conditions, the depressed feeling he first experienced is supplanted by one of exhilaration.

The atmosphere being practically devoid of dust particles and moisture, the light is very intense and we would naturally expect to find contracted rather than dilated pupils; but I find cases in which there is bilateral mydriasis, and this fact but serves to confirm me in my theory of the cause of the anisocoria, namely, that it is due to hyperactivity of the nervous system, which is especially manifest in the cervical sympathetic. I believe that this hyperactivity stimulates equally the radiating fibers of the irides to contract and I account for the unequal dilatation upon the hypothesis that there is a difference in density of the radiating muscular fibers, and it may be of the sphincters also, of the irides.

I further believe that this tendency to excessive dilatation of the pupils is common to those living at so great an altitude and that in cases in which we do not find the anomaly the power of inhibition is sufficient to overcome it.

Case 1.—J. C., age 50, bill poster, resided in Leadville eighteen years. Right mydriasis.

Case 2.—T. C. W., age 25, mining man, lived here two years. Right mydriasis.

Case 3.—H. T. B., druggist, age 25, resided here five years. Right mydriasis.

Case 4.—J. H., age 53, lived here eighteen years. Right mydriasis.

Case 5.—C. H. M., age 30, civil engineer, resided here two years. Left mydriasis.

Case 6.—J. J. M., age 46, furniture dealer, resided here eighteen years. Left mydriasis.

Case 7.—S. G., age 27, salesman, lived in Leadville three years. Left mydriasis.

Case 8.—T. J. W., age 32, physician, resided here two years. Left mydriasis.

Case 9.—T. H., age 34, commission merchant, lived here eighteen years. Left mydriasis.

Case 10.—A. J. B., age 43, saloon man, lived here five years. Left mydriasis.

Case 11.—J. S. B., age 40, mining man, resided here eighteen years. Left mydriasis.

Case 12.—H. S. J., age 21, mining man, resided here one year. Left mydriasis.

Case 13.—C. H. B., age 24, dry goods merchant, lived here ten years. Right mydriasis.

Case 14.—Dr. A. J. McD., age 40, resided here seven years. Left mydriasis.

Case 15.—Ed. L., age 29, harbor, lived in Leadville four years. Left mydriasis.

Case 16.—G., age 35, physician, resided here three years. Left mydriasis.

Case 17.—W. W. W., age 40, stationary engineer, resided in Leadville six years. Left mydriasis.

Case 18.—B., age 30, plumber, lived here four years. Left mydriasis.

Case 19.—D. A., age 28, telegraph operator, has lived in Leadville five years. Left mydriasis.

Case 20.—E. S., age 27, housewife, resided here six years. Right mydriasis.

A SIMPLE, PAINLESS AND PERHAPS NEW METHOD OF VACCINATION: DENU- TION VERSUS SCARIFICATION.

BY M. B. HUTCHINS, M.D.,

CLINICAL LECTURER ON DERMATOLOGY AND SYPHILOGRAPHY, ATLANTA
MEDICAL COLLEGE,
ATLANTA, GA.

This method may fall under the category of "nothing new under the sun," but I have not been able to find that the simple principles followed have ever been put into practice before. The idea of perfecting

a new method of preparing the skin for inoculation was brought to my mind because of my sympathy for little children who are frightened and even given pain by the old, scarification plan.

The protection from absorption possessed by the skin is due to the epidermis and chiefly to the horny layer. This being removed, or even scarified, permits absorption. An excoriation or denudation is necessary to local infection in most cases, though follicular inoculation has been credited. Given, then, an impermeable covering, it was but necessary to find an agent which would dissolve or disintegrate the upper layers of the epidermis without pain or fright to the patient. Salicylic acid in glycerin was tried and discarded. A saturated solution of caustic potash in a 20 per cent. solution of cocain was effective, though the final product of the mixture was uncertain. A light application of the caustic potash stick was tried, being neutralised with acetic acid as soon as burning was felt.¹ This was effective, but acted rather severely, and left some pigmentation from slight inflammation. Finally, ordinary liquor potassæ was tried and found to meet every indication.

The elder Hebra denuded his old eczema patches with green soap and rubbing, and this softening action of potassa has long been well known. We use liquor potassæ in mounting scales and hairs for microscopic examination, and it rapidly disintegrates them. The pigmentary deposits in the epidermis are easily removed after the application of liquor potassæ. Official liquor potassæ is a 5 per cent. solution, that in common use becomes stronger through evaporation.

The procedure of preparing the surface for vaccination is as follows: The point to be vaccinated is cleansed. A piece of cotton as large as the desired denudation is wet with liquor potassæ and laid on, or a little of the fluid is put on with the bottle stopper. After two or three minutes, or as soon as slight burning is felt—it usually does not burn at all—the cotton is removed, if it was used, the soap mixture which has formed with the skin secretions is wiped off with a piece of wet cotton, though this is not essential to success, in order to render the next step easier. Then an ink eraser, a tooth-pick of soft wood, a pencil rubber, a piece of gauze (the quickest) or a piece of damp cotton is used to rub away the softened epidermis. The friction is slight, the pain is only a little stinging when the sensory nerve filaments become exposed. We obtain in a few seconds a moist, shining surface, often a clear view of the papillary vessels but no bleeding. The vaccine is now applied and let dry on in the usual way.

The advantages of this method are its practical painlessness and the absence of terrifying instruments, such as the "Neptune's trident," the lancet or sewing needle. Further, bleeding is a bar to successful inoculation. By scarification it is difficult to stop short of bleeding, while with denudation bleeding is almost impossible. A little girl aged 6 years, vaccinated herself by my method. There is also less danger of an undesired infection from instrument or epidermis when this method is employed.

As to the results: A good lymph will "take"; an unreliable one will not. Inoculation was successful in as many cases vaccinated by denudation as by scar-

ification. Within three days one young man developed twenty-five distinct and characteristic vesicles in an area three-fourths of an inch square. Others "took" in the usual way. Abortive lesions formed in other cases just as after the old method.

One doctor vaccinated seven children in an institution at his first trial of my method. With three he did not wash off the liquor potassæ before denuding; in four he did. Every one of the seven "took." The doctor was fortunate in his lymph. Other physicians have found the method successful. Many cases could not be followed up. Increased experience with the method and the reports of others demonstrate probably a larger percentage of success than is possible with scarification.

Ordinarily there may be one objection to the method of denudation; it is slower, but the time necessary to subdue a refractory child for scarification will often amount to more than two or three minutes. Again, if we draw blood in scarifying, this must all be removed and further flow checked to insure a result; this takes time. For those who wish to save themselves annoyance, or to spare little children and nervous people pain and fright, the method described is preferable. Sympathy and convenience justify its use even if the whole matter is simple and small.

Denudation offers a field for dermic medication which may reduce the necessity for so much use of the hypodermic syringe. I have not experimented here except with cocain and eucain solutions. I obtained their characteristic effects. Something similar to this has been used for the dermic absorption of drugs, viz., the formation of a blister which resulted in the denudation of an absorbent surface. A denudation maintained with moist rubber tissue might spare some ill person frequent, painful thrusts of the hypodermic needle, where such introduction of drugs should be practiced.

NOTE.—This method was demonstrated to the Atlanta Society of Medicine on the evening of Sept. 21, 1897, a report of which will be published. Most of the experiments with the method were made since September 1 of this year, although slight trial of other agents was had some months ago. 311-312 Fitten Building.

THE DRY METHOD IN INTRA-UTERINE SURGERY.

Read before the Illinois State Medical Society.

BY EDWIN WALKER, M.D., Ph.D.

EVANSVILLE, IND.

Last year I read before this society a paper on the abuse of water in surgery (*AMERICAN MEDICAL ASSOCIATION JOURNAL*, No. 26, 1896). Some of the disadvantages of its excessive use in both septic and aseptic cases was pointed out. It was urged also, that outside of hospitals, where we have to rely on unskilled help to prepare the water, it is often used from vessels improperly cared for, and is often the source of infection. On the other hand, there is no longer a doubt that ideal asepsis may be attained by the dry method. The action of the water, though it be pure and sterile, exercises an unfavorable influence on healthy tissues, while antiseptic solutions often injure them and markedly reduce their ability to resist infection. It is practically settled, that septic wounds can not be rendered aseptic by any washing, or the use of antiseptics, no matter how strong they are used; all we can do is to render the conditions such as to give the tissues a chance to exclude the germs.

¹ Since writing the above the caustic potash stick was tried again, in the absence of a supply of liquor potassæ. A minute drop of the deliquescent potash was put on, gently smoothed out and immediately wiped away with damp cotton. The denudation was perfect, the pain nil and the procedure even more rapid than scarification.

It is not intended to inveigh against water used to cleanse the parts before operation, for it is here indispensable, but after the operation is begun it should be dispensed with; nor is it denied that in some septic cases, as ulcers or abscess cavities, it may be mechanically impossible to remove sloughs or other detritus without water. If efficient drainage is established, such cases will not be numerous.

In this paper I will discuss the dry method in intra-uterine work. I believe there has been almost a universal tendency in this direction; personally I have gradually used less irrigation, and now have almost entirely given it up, and my results have since been much more satisfactory.

The most frequent occasion for invasion of the uterine cavity, is to remove the products of conception, and curettage for endometritis, and in these cases I have most extensively employed the dry method. It has been almost the universal custom in these cases to irrigate with plain water, or some antiseptic solution; this is directed by all the standard works on gynecology. Irrigation is superfluous. After a thorough curettage for endometritis or the removal of the placenta, we have a fresh wound which is to be cleaned, the blood wiped off just as from an incision. This can be more efficiently done by wiping with sterile gauze than in any other way. Irrigation is often positively harmful. Who has not seen localized peritonitis after irrigation of the uterus, from passage of fluid through the fallopian tube? Besides, the water or antiseptic does in some degree impair the exposed tissues, and is often the carrier of infection. It is a rule that the simplest method, the one which requires the employment of the fewest things and the least handling, is the one which will most frequently attain asepsis. Water or fluids have to be poured from one vessel to another, and in many ways exposed to contamination.

By the dry method these cases are very simple. In curettage for endometritis, the patient is put in Simon's position and the vagina scrubbed with liquid soap. This is washed out with creolin, and followed by plain water. It is then thoroughly dried with sterile cotton, dilated and thoroughly curetted as usual. When this is done the cavity is thoroughly wiped out with sterilized gauze, the wiping being repeated several times, until the gauze comes out but slightly tinged with blood. Then it is wiped out with iodoform gauze, and packed with the same. I have found it a great help to have the gauze, both plain and iodoform, cut in strips and packed in a glass tube (a large test tube). It is sterilized in these tubes, and drawn directly from them as placed in the uterus, without touching anything but the dressing forceps. If the case is one of abortion, and part or all of the ovum is retained, the same method is followed, except that Martin's curettage forceps are used to facilitate the emptying of the organ. These are dull, smaller and less clumsy than the ordinary placental forceps, and are much more convenient and efficient. The wiping and packing is the same, except that it has to be more frequently done, the hemorrhage is greater, and there are more shreds of tissue to be wiped out. I do not suppose that by this process, we really remove all the membranes; I doubt if we ever do, but this is not necessary, for in aseptic treatment healing will be complete. If the os is patulous and the abortion is as late as the fourth or fifth month, the fingers may be introduced and will greatly aid in the removal of the pla-

centa. I have, however, found the forceps a great aid in these advanced cases, and have never done any damage with them. I have in two instances emptied the uterus for vomiting in pregnancy. These cases had both advanced to about the eighth week. The vomiting was so severe and constant, that after consultation it was decided that farther delay would greatly endanger life. The os was dilated as usual, the ovum was seized with forceps and stripped out, the membranes being extracted in pieces. The cavity was then curetted, wiped out and packed. In neither case did the temperature rise over 99.6, nor the pulse above normal. In both cases the nausea ceased at once, and neither was sick from the anesthetic. It is interesting to note here, that one patient became pregnant a few months later, and was almost entirely free from nausea during her pregnancy. I have a number of times emptied the uterus in a similar manner, before fetus was expelled, after finding that abortion was inevitable. The advantage is, that the patient is spared much suffering and hemorrhage, and the danger is very much less than by waiting for nature to do the work.

I can not leave this part of the subject without a note of warning. It is understood that this method is free from danger only in the hands of those who have sufficient skill to do it properly, and have learned by careful study and experience to do aseptic work. Unless these manipulations are done with care and under strictest asepsis, many accidents will occur. But these are chargeable to the individual, not to the method.

When the contents of the uterus has become septic the method should be the same: dilate, remove contents, wipe out and pack. I feel that my experience in abortions justifies me in commending it as the best and safest. In puerperal cases, my experience has not been sufficient to speak authoritatively, but I do not believe it will prove an exception. In one case of missed abortion, my colleague, Dr. Owen, removed a septic ovum of three and a half or four months, in this manner. The patient became pregnant, the fetus for some reason died between the third and fourth month. Later she had fever. This continued three months. When she came under the doctor's care she was much reduced by long pyrexia; examination revealed the condition. She made a rapid recovery. This case was an excellent test; notwithstanding the ovum was torn out, and not a drop of water was used, the result was perfect. In ordinary cases where the fetus has been expelled and the placental membrane remains, and fever has set in, the dry method leaves nothing to be desired.

The only cases in which there is any doubt of its efficiency, are the puerperal or later abortions, in which the uterus is markedly affected and a large amount of pus or septic material is found. These are the cases in which frequent or constant irrigation has been recommended, and in many cases is doubtless successful. In private practice this is a very difficult method to carry out. It is not safe to trust it to a nurse, and it requires almost constant presence of the physician, and besides, in many cases it fails. I believe the manual disturbance in these cases, is, in many instances, bad. The barrier against infection, which nature throws out around any area to shut off systemic infection, is often broken down by such frequent interference. It may be urged that the packing would be, but this latter need not be so often done, and if carefully executed would not do as much violence as the

intra-uterine douche. If this could be replaced by packing which would not require removal oftener than once or rarely twice in twenty-four hours, it would be a great gain. The gauze takes up much of the discharge and keeps the os open, thus securing drainage. I have recently used the packing in two cases, one of which recovered, but in neither case was it a fair test, as it was not begun early, nor was it used alone.

A CASE ILLUSTRATING THE VALUE OF SYMPHYSIOTOMY WHEN A TUMOR OBSTRUCTS THE PARTURIENT CANAL.

Read before the Denver and Arapahoe County Medical Society, February, 1897.

BY H. W. ROVER, M.D.

LECTURER ON THERAPEUTICS, DENVER MEDICAL COLLEGE.

AND T. MITCHELL BURNS, M.D.

PROFESSOR OF OBSTETRICS, GROSS MEDICAL COLLEGE.
DENVER, COLO.

PART I.—BY DR. ROVER.

INTRODUCTION.

Based on two cases of symphysiotomy which occurred in my private practice (one operated on by Dr. Gustav Zinke of Cincinnati, and the other by Dr. T. M. Burns of Denver), and both of them successful to mother and child, I desire to give expression and emphasis to the benefits derived from said operation.

The operation, though a feasible one, does not suggest itself to every medical mind interested in any particular case. The patient was seen repeatedly by three physicians during the latter part of her pregnancy and no unanimity of opinion could be reached; not even after she was taken in labor did the various counsel agree. One favored a Porro, the second a craniotomy, I pleaded for a symphysiotomy. Why this discrepancy of opinion? Simply because the respective indications, benefits and limitations for either of these operations are not definitely fixed.

It may be said that under favorable conditions and at the hands of skilled operators, the death-rate has been almost *nil*. Pinard lost but one mother in his first twenty operations, and Sweifil one in forty-three cases. The fetal mortality, including those that die shortly after birth, runs higher; according to Neugebauer as high as 20.5 per cent.

Cæsarian section, although more saving to child life, is more dangerous to the mother. Induced premature labor under approved modern methods with its low maternal death-rate, is more hazardous to the fetus than is a symphysiotomy.

Where a symphysiotomy is possible and the child *in utero* is viable, we should never think of performing a craniotomy. In this connection I recall the teachings of an old professor (Dr. Tate of Cincinnati) who declared that an unborn child, whose life is being held at stake, may prove to be an unborn Milton or Shakespeare; hence the conclusion that if other safe measures can be instituted the fetal life is not to be sacrificed.

The woman's powers of locomotion are not necessarily crippled by slight looseness of the joint, and as a rule, under a rigid asepsis and with complete immobilization of the pelvis during convalescence, the restoration of the symphysis in women not previously infected is complete. In both of my cases the union was perfect, in the first, great precautions were taken to secure the immobilization of the pelvis by the use

of both adhesive plaster and a jacket of plaster-of-Paris; whereas, in the second case only a strong linen many-tailed bandage held the parts together.

The operation is best adapted to the symmetrical rachitic pelvis, and should not be undertaken when the true conjugate is less than two and five-eighths inches. As much as two to three inches of separation may be secured without risk of injury to the sacro-iliac symphysis. Version should not be resorted to when the head can be made to engage.

Case report.—Mrs. K., German, aged 35 years, married seven years; childhood history negative, no rachitic tendencies.

Her labors: 1st, at nine months vertex, terminated by craniotomy after nine hours of labor; 2d, at nine months vertex, terminated by podalic version after five hours of labor; 3d, at eight months breech, terminated by inducing labor with the catheter. Catheter was in place six hours before labor set in, the labor lasting six hours; 4th, occurred under my supervision Aug. 10, 1895. When consulted beforehand I advised a symphysiotomy, but the patient had been instructed by the physician in charge of her previous confinements that a premature labor induced at the seventh month, and the mother during her pregnancy resorting to a vegetarian diet (particularly fruit), would offer the best hope for a successful issue on the part of child and mother. As in the third pregnancy, the catheter was introduced but remained in place for two days before labor set in. The labor lasted six hours and the presentation was a breech. Unfortunately prolapse of the cord occurred early in the labor, and as its result a dead baby was born; 5th, this was terminated by the symphysiotomy reported in this article and resulted in saving both child and mother.

The puerperal state in each instance was normal, and with the exception of the last she was up on the eighth day. Her various pregnancies were all normal.

History of tumor.—Patient never felt any tumor or symptoms from it. At the first labor (which took place in Germany) the attending physician diagnosed a contracted pelvis due to the sacral prominence projecting abnormally forward; at the second labor she had the same physician and consultant. There was nothing new with reference to the obstruction. At the third labor she had the same physician. I advised symphysiotomy during the fourth, but by request induced labor at seven months. All I could make out was a dystocia due to abnormal size of the promontory. In all of the first four pregnancies the child was still-born but living until artificial aid was used.

Her last labor, the fifth, began July 27, 1896, at 7 A.M., and the waters broke at 2 P.M. I saw her at 3 P.M., and a little later the other two consultants were at the bedside. No unanimity of opinion, as before stated, could be reached, each of the three physicians contending for his choice of operation. The family decided against the Porro; the vitality of the child decided against a craniotomy, and hence about 5 P.M. Dr. Burns was called in to perform the symphysiotomy, he advocating this measure. Her previous pregnancies, with their respective terminations, warranted the step taken, and today there is happiness in a Denver home because of such a proceeding.

PART II.—BY DR. BURNS.

THE OPERATION, SUBSEQUENT TREATMENT AND RESULTS.

By abdominal palpation, the presentation was found to be a vertex, and the position a left occipitoposterior. The forehead was prominent on the right side above the brim, an indication of some obstruction to the engagement of the presenting part.

By pelvimetry, the distance between the anterior superior spines was ten and one-half inches, the crests eleven inches and the external conjugate seven inches. These measurements indicated that the dimensions of

the pelvic inlet were normal, except slight diminution of the internal conjugate.

By vaginal touch (patient under chloroform for introduction of hand), the pelvic canal was apparently normal, except for the presence on the upper half of the anterior surface of the sacrum of a tumor, seemingly the size of a child's head and of a consistency similar to a chondroma or a fibroma.

The opening at the brim was barely large enough to allow the passage of my closed fist (a circumference of about nine and one-half inches). The cervix was found dilated to the size of the space not occupied by the tumor at the inlet.

Considering the size of the head, the difference which symphysiotomy would make in the dimensions of the inlet, and the more or less compressibility of the tumor, shown by the history of the previous cases, I stated that with symphysiotomy and the careful use of the forceps a living child could be delivered.

The operation.—The abdomen, vulva and vagina were rendered aseptic. The instruments were sterilized in a wash-boiler. The patient was chloroformed and placed on the kitchen table; a Kelly pad was formed of an oilcloth, the head of the table being raised by a brick under each leg, and the hands of all were rendered aseptic. A medium sized straight Peaslee's dilator was passed into the bladder to deflect it away from the pubic joint. A longitudinal incision was made through the muscles over the upper part of the symphysis, and through this incision the index finger was passed behind the pubes. By a straight and a curved bistoury the joint and sub-pubic ligament were incised. At times cutting from before backward to better prevent any injury to the soft parts was employed. Then the pubic joint was carefully separated, while the assistants held the thighs. This was followed by rather severe venous hemorrhage, which was arrested by hemostatic forceps and absorbent cotton compresses dipped in hot water. The forceps were applied to the head above the inlet. As traction was made separation of the symphysis to the extent of two to two and one-half inches was required before delivery could be effected, although the tumor flattened somewhat. (During delivery the anterior cervical and vaginal wall prolapsed, but were replaced and held in position. There was no tear in the perineum.) After the delivery of a small placenta, the Peaslee dilator was reintroduced and held as before, while the edges of the pubic joint were brought into apposition by pressure on the great trochanters. Then, after the hands were made aseptic, the muscular incision was closed by catgut sutures and dressed with boric acid, iodoform gauze and absorbent cotton. A many-tailed thigh and hip bandage of linen crash, and a many-tailed abdominal binder of the same material, reaching from the breasts to below the great trochanters, were the only means used to keep the edges of the pubic joint in apposition. The double bandage thus formed about the hips is all that is necessary to hold the joint in place, and being many-tailed allows a portion of it to be loosened and the wound dressed without the joint being disturbed.

After the operation the patient's pulse was 96. The child, a male, was somewhat asphyxiated when born, but was quickly resuscitated by the Forrest method. It weighed six and one-half pounds.

The puerperal history.—The temperature and pulse were highest on the afternoon of the first day, viz., 100.2 degrees F. and 100, respectively. During the

next twenty-eight days the temperature varied between normal and 99.5 degrees F., and the pulse between 96 and 72. The bowels were moved by an enema on the third day, and subsequently kept active by enema and compound licorice powder. The urine was drawn twice on the first day, but after this it was spontaneously voided without pain. The lochia was slight and continued three weeks. On the third day it became offensive, but the odor disappeared the next day from the use of the vaginal douche. Twice on the twelfth day a large amount of dark blood was expelled from the vagina, each time just after the bowels had moved. This was probably due to the patient being continually in the horizontal position. The vaginal douche was used the first three weeks. After-pains were present on the first two days. Pain and tenderness were absent except slight headache and pain referred to the hips at times, and some tenderness about the wound.

The wound was examined on the fourth day, and was found to be tender and red. This resulted from the catgut sutures being septic, or the lochia coming in contact with the wound when the patient turned on her side, or the mechanical irritation caused by the change of posture. The wound was redressed after being bathed with bichlorid. On the fifth, sixth, seventh, eleventh and fourteenth days the wound was cleansed by the use of alcohol and hydrogen dioxide, and dressed with an ointment (composed of equal parts of bismuth and castor-oil) and then iodoform gauze, etc., applied. On the seventh day the sutures were removed because they were partially absorbed.

The position of the patient was the dorsal till the third day, when she turned onto her left side. This was accompanied by slight pain. The patient was allowed to continue this position at times because it was believed that the lateral posture would keep the joint in as good apposition as if she was in the dorsal decubitus, better allow the lochia to escape and especially relieve the severe strain and worry which one constant position causes, and the only harm that could result was considered to be infection of the wound from the lochia, and this could be prevented by not placing the patient fully on her side until the wound had completely healed.

On the fifteenth day the patient sat up in bed. On the seventeenth day she walked across the room and sat on a chair twenty minutes, but felt motion and pain in the joint when walking. On the twenty-fourth day she was up five hours, could stand straight, but her right hip appeared lower and she seemed to rest her weight on it; she could feel no motion at the joint, but at times when walking this right hip seemed to drop. On the twenty-eighth day the patient resumed her household duties with nearly her usual strength, and no disturbance of the pelvis.

A pelvic examination four months after the birth of the child, showed the cervix to be a little low and bilaterally lacerated. Bulging from the upper part of the anterior surface of the sacrum was a hard round tumor, which in size and shape could be likened to a flattened orange. All of the sacrum which could be felt was of normal size. I do not believe that this condition is due to a bulging of one of the sacral vertebrae from spondylitis because of the shape and the fact that during labor the tumor flattened. By abdominal palpation nothing could be found because of the tenseness of the muscles. The distance between the tumor and the pubic symphysis was between two

and two and one-half inches, estimated by separating the index from the middle finger at the inlet and then measuring this separation by the tape after the hand was withdrawn.

In conclusion, we may say that this case not only illustrates the value of symphysiotomy when the pelvic canal is obstructed by a tumor, but also that even wide separation of the symphysis is not necessarily followed by any after-effects: that the patient need not be kept in the dorsal decubitus, and that many-tailed linen crash bandages are all that are necessary to keep the joint in apposition. Further, as stated in my previous article, this operation can be as successfully performed in a private house as in a hospital.

I wish to here add that in the "Transactions of the Colorado State Medical Society" for 1896, can be found two cases of symphysiotomy reported by me and that I have subsequently delivered the first of these two patients successfully by means of a very easy high forceps extraction.

FATTY HEART WITH BRADYCARDIA, WITH A REPORT OF A CASE.

Read before the North Chicago Medical Society, October, 1897.

BY CHARLES J. WHALEN, M.D.

INSTRUCTOR IN LARYNGOLOGY, RHINOLOGY AND DISEASES OF THE CHEST
IN RUSH MEDICAL COLLEGE; INSTRUCTOR IN SURGERY IN
CHICAGO POLICLINIC,
CHICAGO, ILL.

The subject of fatty heart should be of the greatest importance to examiners for life insurance companies, and one that should be very thoroughly understood by the medical practitioner, for a great deal of misery and unhappiness has been caused by careless or thoughtless medical opinions expressed regarding presumed fatty degeneration of the heart.

I can recall more than one instance of men going about with the greatest caution, firmly impressed with the idea that following the slightest shock of exertion they were to die suddenly. This impression was gained from the ignorance of doctors, and on examination of the heart it would be found in very good condition.

By the name "fatty heart" we mean two quite distinct conditions, one an abnormal deposit of fat in the heart, and the other, a fatty degeneration of the muscular fibers.

The first consists in an increase in the amount of fat that is normally found in the sub-pericardium after the sixth year of life. The connective tissue becomes infiltrated with oil globules, and it always occurs in great general corpulency. It is of little importance when confined to the sub-pericardial layer, but when it extends to the connective tissue, that links together the muscular fibers in the myocardium, it produces weak spots in the cardiac walls which greatly reduce the heart's force, and is apt to be followed by serious results.

In fatty degeneration the sarcous substance itself is transformed into fat globules, and comes from the decomposition of albumin in the muscular cells. The structure of the heart degenerates and portions are transformed into fat granules. It is within the substance of the muscle and along the longitudinal fibers that the transformation into fatty material first takes place, the myocardium being particularly prone to undergo fatty degeneration.

If the deposit of fat is localized the heart has a mottled appearance, but later, when the heart becomes

generally involved, it has a "yellow brown or buffy color," the tissue may become so utterly destroyed that they break down under pressure.

Etiology.—Fatty heart is occasionally observed in early adult life, and has been found even in the fetus; as a rule it should be remembered that youth is not the season of fatty heart. Even middle life is not very frequently its seat, but it is found in people past the meridian of life, who have broken themselves down with drink and debauchery. It is much more frequent in males than in females. It is ascribed to imperfect oxidation of the nitrogenous constituents of the muscular fiber produced by general debilitating causes, such as wasting diseases, failing nutrition of old age, phosphorus poisoning, prolonged fevers producing parenchymatous degeneration. Occupation plays a very important part in its causation. A man who leads an active life up to 40 years of age, and suddenly changes to a life of idleness, is very apt to suffer from fatty heart. Other causes are obstruction of the coronary arteries, compression of the heart from abdominal tumors causing degeneration and valvular disease, especially in cases where there is great hypertrophy of the cardiac walls. Alcoholic abuse and the taking of great quantities of fluid by a fat person certainly predisposes to fatty heart; too much stress should not be laid on obesity as a predisposing cause.

Symptomatology.—"Fatty degeneration of the heart" always plays a far larger part in popular speech than it does in reality. It is a fact that many patients complain of a peculiar feeling, a sense of weakness, of suffocation or fulness under the sternum, pain or numbness in the arms and a cold creepy feeling down the back; later in the disease there is precordial pain, dyspnea, attacks of syncope, which may simulate apoplexy, except that it is not followed by paralysis; angina pectoris and cardiac asthma may come on, and death may follow with increasing dyspnea and general edema. I have seen three cases in which postmortem revealed well marked cases of fatty heart, which during life presented no special cardiac symptoms. The physical signs are as uncertain as the symptoms; there may be found an increase in the area of cardiac dullness, a small and sometimes irregular pulse, indistinct first sound, accompanied by a generally weak condition of the entire organ, although in pernicious anemia there may be quite a strong and perfectly regular pulse up to death in spite of the most marked fatty degeneration. A pulse permanently slow or permanently fast, is a sign of great value, although either may be found in a perfectly healthy person. I have seen a case in which the heart beat was forty-eight per minute: a condition which had been noted by other physicians during his early adult life; he also claimed that a brother had a similar pulse rate. Arcus senilis may occur with or without fatty degeneration of the heart.

Diagnosis.—Our power to diagnose the disease during life has not kept pace with our ability to recognize it after death. In many cases the diagnosis can only be arrived at by careful consideration of the whole aspect, and then it is often a matter of conjecture rather than of certainty; yet, how often do we see a diagnosis made in an off-hand manner by men not remarkable for the extent of their information or their skill in diagnosis. We can best arrive at a probable diagnosis by first excluding other possible diseases, and combining the symptoms with the history, we may reasonably suspect fatty degeneration if we have

a patient past middle life who is the subject of gout, alcoholism or a wasting disease, if in addition to the above we find atheromatous changes in the blood vessels, or degeneration elsewhere, such as arcus senilis, together with weak, irregular and at times intermittent permanently slow or fast pulse. Presence of angina pectoris, edema of the feet, Cheyne-Stokes respiration, with pseudo-apoplectic attack, all tend to confirm a suspicion of fatty heart.

Prognosis is always unfavorable, but by regulated habits and medical treatment life may be greatly prolonged. Between 80 and 90 per cent. of cases of fatty heart die suddenly.

Treatment.—In fatty infiltration the treatment is practically the same as for obesity. The most satisfactory method is by reducing the quantity of food taken in twenty-four hours, together with plenty of exercise. The patient should be allowed to partake moderately of a mixed diet. The foods rich in albuminoids should be diminished least of any, because it would be sure to work injury to the system if it were supplied in too small an amount. The fats and starches are more potent in increasing adipose tissue and in shielding from oxidation the fat already stored up in the body. A varied diet is extremely desirable for one who is corpulent, and we should exclude neither fat nor starch fully from the dietary, but merely limit the amounts to be taken. Every case must be treated as an individual one and receive careful consideration. I know of no remedy taken internally that has the power of reducing fat, unless it is phytolacca, which has been so highly recommended by numerous members of the profession. My experience has taught me not to look upon it with much favor.

In fatty degeneration a number of remedies have been recommended; some are very useful, such as arsenic or iron. Whatever treatment is adopted must be continued for some time. There is no plan of treatment that can restore the degenerated muscular fibers. The principal thing is to improve the tissue making power of the blood; this is best accomplished by iron, cod liver oil, strychnia, nutritious diet, fresh air and out-door exercise; violent exercise or mental excitement are to be avoided. In cases where there is no atheromatous degeneration, the heart muscle can be greatly strengthened by having the patient take moderate exercise, but never to the extent of causing dyspnea. In this way the myocardium is strengthened and its functions are increased. Blisters applied over the precordium have been known to give relief when cardiac stimulants have failed. Dr. B. Robinson, in a case where other remedies had failed, was able to obtain marked temporary relief from dyspnea by the Paquelin cautery applied over the precordium at sixty or seventy points.

In conclusion, I give briefly a history of a case of fatty heart with bradycardia followed by death five weeks after beginning treatment.

Jas. R., American, 54 years of age, of medium height, rather spare build, weighing 140 pounds, fairly well nourished, came to me August 23, 1895, and gave the following history: Had been a free drinker of malt liquor and spirits; never had rheumatism or venereal disease; for two weeks he had been having dyspnea on exertion, especially when going up stairs, some cardiac palpitation and considerable edema of the feet and legs. Examination of the chest revealed the signs of a dilated heart; apex beat was one-half inch outside the nipple line and in the sixth interspace. Heart sounds were not as intense as normal and were heard loudest four inches below the nipple, and were audible at the outer border of the mammary region and heard almost as distinctly at the sternum. In other words, the sounds

at the apex could be heard over an area of nine inches, from the sternum to the axilla, and from the nipple to the eighth interspace, a distance of four inches, showing we had considerable hypertrophy of both the right and left ventricles.

His circulation was poor, as evidenced by the blue color of the hands and feet: pulse was slow, regular and very soft, and beating thirty-two to the minute: no atheromatous changes could be detected in the arteries.

I made a diagnosis of fatty heart and forbade him leaving the house, placing him upon the usual heart tonics, nitroglycerin gram 0.0006, t. i. d., nux vomica, with small doses of digitalis every four hours, together with iodid of potash in 0.32 to 0.65 gram doses. There were signs of improvement for a few weeks, his pulse rate having increased at one time to forty-eight beats per minute, but very little increase in strength was perceptible. By September 25, one month from the beginning of treatment, his limbs had become so edematous that I was obliged to make several scarifications, which afforded him marked temporary relief.

He disregarded my instructions and had continued his occupation up to the day before his death, which occurred without any premonition October 1, just five weeks from his first visit to me. He probably would have died at his post except for the extreme methods to which I resorted to prevent his leaving the house on the day before his death. I afterward learned that he was at his work every day except that on which the scarification was made and the one just preceding his death.

Postmortem was made three hours after death; rigor mortis present: internal organs were found normal, excepting the heart, which was extremely large, weighing twenty-two ounces: from the upper portion of the auricle to the apex it measured seventeen and one half centimeters; lateral measurement fifteen centimeters, and six centimeters in thickness. All the valves were found competent and thickened in substance. The cavities were all dilated, a blood clot being found in the right ventricle. No atheroma of the coronary artery were found. Ventricular walls were slightly hypertrophied. The heart had a mottled appearance due to an excess of fat in spots. The muscular fibers were found diminished and much degenerated.

REPORT OF TWO CASES OF HEART DISEASE.

Read before the Mississippi Valley Medical Association, Oct. 7, 1897.

BY JOHN M. BATTEN, M.D.

PITTSBURG, PA.

W. H. M., age 68 years, married and the father of two children; was always temperate and correct in his habits. He was without any hereditary taint and belonged to a long-lived healthy family. He had never been sick but once, about fifteen years ago, when he had a severe attack of acute pneumonia. Since then he has been affected with a cough which annoyed him but little till a year ago, when it became more noticeable. I prescribed for it two or three times during the last year but the cough did not improve.

May 28, 1895, at 11 p.m., I saw him professionally. There was extreme dyspnea; clothes about him in bed were wet with perspiration. His pulse was very weak and rapid, extremities cold, countenance anxious and heart feeble. He had been at a lodge meeting that evening and felt the attack coming on while there. It was with great difficulty, with the aid of a friend, he was enabled to reach his home three squares away. I prescribed for him digitalis and whisky and applied heat to his extremities. With this treatment he was relieved in a few hours, and in a few days went to his business, which was that of a lumber merchant. My diagnosis was insufficiency of the mitral valve with irritability of the heart.

July 15, 1895, he had a second attack very similar to the first, which was treated in the same way. It occurred about the same time of day. On the evening of July 18, patient had a third attack, similar but more alarming than either of the other two. In this attack circumscribed congestion and pneumonia developed in the region of the heart, due probably to

insufficiency of the mitral valve, which caused regurgitation of the blood, driving it back into the pulmonary veins, thereby causing acute circumscribed pneumonia. From this attack patient remained in bed and at his home till Aug. 29, 1895, when he went to his business.

Sept. 4, 1895, at 11 P.M., he had a fourth attack, in which the symptoms were more alarming than those of the previous three. This attack was also followed by acute circumscribed pneumonia. He remained in bed three weeks and did not leave his home till Dec. 4, 1895. He then went to his business. These last two attacks I treated as the first. During the intermissions I put him on iodid of potash 0.65 gram, bichlorid of mercury 0.0016 gram, tincture of digitalis 0.62 c.c. and nitrate of strychnia 0.0016 gram three times a day. He remained at his business till January, 1896. Afterward he was sent to a sanitarium at Cambridgeborough, Pa., where he died May 25, 1896, with what was claimed to be acute Bright's disease. Frequent examinations of the urine, during my attendance, showed that his kidneys were perfectly healthy.

Mrs. T. M., aged 53 years, died March 16, 1897. She was the mother of three children, all living, and was of a scrofulous diathesis. She had had an intermittent pulse thirty years and was short of breath on ascending stairs. For the last year her heart had a strong beat in systole becoming weaker in diastole, still weaker in the next systole and weaker still in diastole, then an intermission. The heart would then repeat as before. The beats were quicker than normal. This condition I attributed to valvular disease accompanied by hypertrophy and irritability of the heart. In December, 1895, she had edema of the legs, but this subsided under treatment in about two weeks and she was reasonably comfortable till Oct. 10, 1896, when I examined her urine and found albumin, specific gravity 1040; there was edema of the legs. October 21, her urine showed only a trace of albumin; legs still edematous. November 8, edema extended to the thighs and body, right arm and right breast, together with ascites. About this time pneumonia developed. November 12, there was 8 per cent. of albumin in the urine. The rusty coated sputa subsided and cough diminished. November 16 she was still expectorating a muco-purulent matter, breathing quick and labored. December 13, I punctured the abdomen with a trocar. Very little fluid ran through the cannula. On removing the cannula, the abdominal fluid dribbled for about three weeks through the opening made by the trocar. For three weeks previous to tapping the patient was unable to lie down. Afterward for a time she was able to take the recumbent position; the albumin disappeared, the cough ceased and the urine cleared and was normal in quantity. This condition continued till the puncture healed. Then the ascites increased so that the patient was unable to lie down after Christmas, 1896. Jan. 18, 1897, I again performed abdominal paracentesis to relieve dyspnea but, as before, the fluid only dribbled for a time through the puncture. During this time the ascites and edema diminished considerably. Since October, 1896, fluid oozed through the skin of her legs in abundance and caused gangrenous ulcers. She died of uremic poisoning and was affected with this a week before her death. The treatment consisted of tonics, diuretics and cathartics. After the first tapping there was no albumin found in the urine.

The general symptoms of these two cases ran in about the same line, ending in death in about the

same way, pressure from ascites interfering with the function of some organ. It also serves to develop what is too often true, that the physician called late in the course of the disease, is apt to overlook the primary disease and make his diagnosis according to the most prominent secondary condition that exists at the time.

The history of the first case would exclude Bright's disease as the primary disease and cause of death. A patient with such a history could have had Bright's disease of the kidneys only as a secondary condition. The second case could have been with much assumption of truth diagnosed either albuminuria or acute pneumonia, at the time either of them was most prominent.

THE NEW ELECTRO-MERCURIC TREATMENT OF CANCER.

Read before the American Electro-Therapeutic Association, at Harrisburg, Pa., Sept. 22, 1897.

BY G. BETTON MASSEY, M.D.

PHILADELPHIA, PA.

In a limited series of cases in which accessible and supposedly still local carcinomas and sarcomas have been more or less perfectly subjected to this method I have had two well-proven cures and four or five cases now progressing toward the same happy result. Some of these cases date back to 1893, when I accidentally noticed the good effect of a mercurial coating on a zinc anode in contact with a cancerous ulceration, and began the treatment with dosages of 100 and 150 milliamperes with combined mercury and cocaine cataphoresis, but my own estimate of the value of the method received an immense impetus during the past spring on the occasion of the first employment under general anesthesia of 500 and 1,000 milliamperes to a carcinoma of the breast. The usual effect of a local necrosis about the zinc-mercury electrodes occurred and the tumor shrank perceptibly at once from a cataphoric dispersion of its liquid contents; but a most important fact was noticed the following day when the dry dressing was removed: it was then seen that the puffed, purplish, malignant, appearances had disappeared beyond the area of necrosis, the skin and subcutaneous tissue now lying flat and pink to a considerable distance from the electrode. This proved that a substance, or influence, had passed from this amalgamated electrode through the malignant tissue, that had a lethal effect on the cancer cells while failing to hurt the normal tissues containing them.

The key to the results in all the cases was contained in this single observation, and I predict that few, if any, discoveries in medicine have surpassed this in practical importance, for it not only gives conclusive proof of the correctness of present pathologic views, which regard cancer cells as primarily local and possessed of a low organization and vitality, whatever their true nature may be, but, more important still, indicates a remedy for accessible cases of this increasing scourge of mankind.

The special value of a method that enables us to project a nascent oxychlorid of the most powerful antiseptic into the tissues at will, probably into the interior of the very cells themselves, is theoretically evident. It also appears that a greater portion of the mercury-laden current will traverse the cancer prolongations than the surrounding tissues on account of the lessened resistance due to increased vascularity of the morbid tissue. Theoretic considerations

thus unite with observed facts in indicating that this method is one of extreme value in local malignant growths.

It would be interesting to ascertain the amount of mercury, by weight, that can be carried into a growth per milli-coulomb, also the distance which it will traverse per volt-hour. I find a table in Lodge's work which gives the cataphoric speed of seven substances, of which hydrogen is the most rapid, traversing an electrolyte at the rate of 1.08 centimeters per hour per volt. Lithium is the slowest, at 0.094 centimeter per volt-hour. Taking 0.1 centimeter per volt-hour as a probable figure for mercury, it would mean that 100 volts of current would cause mercury to travel 10 centimeters per hour, or only 1.4 centimeters in ten minutes. These facts have much practical importance, indicating that we must have a sufficient duration of the current to secure proper penetration, and that amperage alone, while governing the amount and density of the penetration, is incapable of increasing its extent without adding a time element. Since seeing this table of Dr. Lodge I have been convinced that some of my applications have had an insufficient duration. The exact cataphoric speed of mercury should be determined.

The practical details of this method, as applied by me to the cure of cancer, consists of two selective procedures, the gradual and the rapid, adapted to different cases and conditions of malignancy. The gradual method is simply an intensification of a method used by me daily in the cure of obstinate catarrh of the uterus and similar conditions, in which an amalgamated zinc or gold electrode is applied to the ulcerated surface and as much mercury driven in, by daily applications, as the moderate pain produced will permit. This is adapted to incipient cancers and very bad inoperable cancers in which the rapid method is injudicious.

In the rapid method the patient is thoroughly anesthetized; two or three large indifferent pads are placed under the back and connected with the negative pole of the battery. To the positive pole a multiple-connection cord is attached which is to be connected to one or more lancet electrodes, when the latter have been inserted into the growth. Usually an opening must be made into the tumor for the insertion of the electrodes. After being troubled in several cases with the bleeding which this causes, the only blood-loss of the whole method, I attached a separate steel spear electrode to the negative pole and, with this made an electrolytic opening of the proper size. This requires reversing the current for the first insertion, but after the first electrode is in place the current may be turned off at the controller, reversed, and turned on in the proper direction, with one electrode acting. The spear may now be attached afresh to the same binding post that is connected to the pads, and used to make additional openings, into which fresh zinc electrodes are placed and put in connection with the multiple-connection positive cord. No blood will be lost or obscure the field of action.

Five hundred milliamperes is the greatest current so far used in this monopolar method, as this amount has depressed the breathing by a tetanic contraction of the diaphragm. This was doubtless due to the fact that one of my dispersing pads was on the abdomen and the other on the back. In the next case I shall place both pads on the back.

In two cases I have hurried the local dissemination

of the mercury, by placing a cotton-covered disc, saturated with liquor potassii arsenitis on the center of the tumor, as the negative pole, cutting out the dispersing pads. The application now being bipolar and mainly local, the current was increased to 1,000 milliamperes. It will be noted that this application produced a valuable cataphoric action at each pole, mercury going in at the anode and arsenic at the cathode.

After sufficient local effect has been produced the application is terminated and the patient put to bed. At the end of twenty-four hours the slough that has been produced, will be found to be surrounded by an area in which the cancerous manifestations have been quelled entirely, or partially, in accordance with the thoroughness of the application, without the sustaining tissues being necrosed. The slough, itself, is largely aseptic and will come away in about twelve days, permitting us to determine whether a repetition of the process is necessary. The cavity left fills up readily by granulation.

NOTE.—At date of publication the two cured cases mentioned continue well. Three additional cases of completely successful removal of cancerous tumors by the method have since been added to the list.

THE NEED OF DENTAL INSTRUCTION IN MEDICAL SCHOOLS.

Presented to the Section on Stomatology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY EDWARD BRANIGAN, D.D.S.

BOSTON, MASS.

There is a great need of dental instruction in medical schools. Physicians should know more about the teeth than they now do, and when medical students are given a better knowledge of the teeth and of the many disturbances they cause, then will medical science do more for humanity than it is now doing. More than a dozen years spent in looking into the mouths of my neighbors, at the rate of hundreds of mouths a week, has revealed to my observation so many instances of improper treatment of diseases caused by the teeth, that I have long felt it my duty to protest, and I now take advantage of the opportunity given me to put my protest into the relation of experiences that have come to me so many times that I put them forth as cold facts. I shall confine myself to the narration of a few of the more common instances of mismanaged treatment of diseases caused by the teeth. The evils I speak of are common.

Abscesses caused by pulpless teeth are still poulticed and opened on the face by medical men. I have seen many hundreds of these, for this treatment never effects a cure, and in the course of time it dawns upon the patient, if not upon the doctor, that dental assistance is needed. How much better it would have been for the patient to have been sent to the dentist at first and so avoided days and weeks of misery and the necessity of carrying a hideous scar for life. People are still being stabbed on the face and neck because a third molar sometimes causes trouble in trying to get up into the mouth where it belongs. The medical treatment for these simple abscesses is sometimes varied a little. The sufferer may be kept in bed for a time, with temperature and pulse watched, and medicine changed at intervals, according to the symptoms. This sometimes happens when the old tooth-root, at the bottom of the trouble, is so loose that the owner

could pull it out with two fingers. Pus from an abscessed tooth is frequently discharged into the antrum. The extraction of the tooth, followed by proper treatment, would rob the medical profession of many patients who are supposed to suffer from, and are treated for, catarrh. Serious throat diseases are frequently caused by pulpless teeth and sometimes by unerupted or retained teeth. All throat specialists are not aware of this fact.

A more intimate knowledge of the mouth and teeth would help other specialists, aurists, for instance. Severe and painful inflammations of the ear, caused by teeth, are common. The removing of fillings from pulpless teeth has made many sufferers from improper aural treatment happy. Unerupted wisdom and occasionally unerupted supernumerary teeth are the cause of many obscure ear troubles. Next to the dentist, no one needs dental knowledge more than the aurist. Oculists are now tracing a variety of diseases of the eye back to the teeth, but they have not yet found out all the mean things a diseased tooth can do. Many sufferers from irritation of the eye, backed up by an inflamed tooth, do not get to the oculist, and if the general practitioner knew more about the teeth as a cause of disease, he would not in so many of these cases prescribe an eye-wash, or glasses, or a tonic; he would send the patient to a dentist.

A tumor of the nose may be caused by a dead tooth-pulp. Treatment of the tumor without a knowledge of the cause is not calculated to make the owner of the nose happy. The victims of so-called neuralgia, who after weeks and months and even years of anti-neuralgic drugging, die or find relief at the hands of someone who knows something about teeth, are countless. Thousands of people are today being drugged for neuralgia who are really suffering from some form of dental irritation. A pulp-stone no larger than a pin-head can bring about so much pain and loss of sleep, appetite and health that nervous prostration may be, and often is, the end of an affair that a pair of forceps would have ended in a moment.

Bicycle riding has given relief to many sufferers from dyspepsia, but many more dyspeptics would get better if their medical advisers insisted upon their having all their lame and tender teeth cared for. Among the hundred or two of mouths opened every morning for my inspection, I never fail to find a number showing evidence of being used on one side only, and in many of the mouths the front teeth are the only ones that do any work.

Physicians should also take into consideration the constant presence of pus in the mouths of many of their patients. They do not all do this. I find pus in physician's mouths about as often as I find it in the mouths of other classes of patients.

The authorities in charge of the management of hospitals should know more of dentistry. If they did, the nurses and other hospital attendants would know how to cleanse a patient's mouth, and the hospital surgeon would know how to look into a patient's mouth intelligently. The removal of half or a whole jaw for necrosis, would not take place when the extraction of a few roots and the use of an antiseptic mouth-wash would effect a cure. When hospital surgeons know more about the mouth and jaws we shall not be obliged to meet people who have been dismissed from hospitals after some weeks of treatment for broken jaw, with the fracture ununited or with the union in so erratic a form that the sufferer can not close his jaws. When

some one about the hospital is able to examine a mouth we shall not be called on to help the man who takes his broken jaw away from the hospital after having been assured that he will be all right in a few days if he puts a poultice on his bruised face and takes a few pills. It is a fact that some surgeons can not locate a fracture of the jaw, and it is also a fact that when located, fractured jaws are sometimes treated by being bound together with a four-tailed bandage, and then, as a happy afterthought, a couple of front teeth are pulled out to make a hole through which to tuck the patient's nourishment.

After dental instruction is given to medical students, the army and the navy will get a little much needed dental service. They get very little now, although hospital stewards are supposed to be able to pull teeth.

The medical directors of public institutions will find a vast amount of good work ready for them when they realize the importance of having dental service given to those in their charge. A few years ago I discovered that not one of the 500 children in one of the public institutions in my city had a tooth-brush. The children of that institution are now supplied with tooth-brushes, but I fear there are many similar institutions in the world where the tooth-brush is never seen and the dentist never heard of. I am sure that this evil will be corrected very soon after dental instruction is given to the future medical directors of public institutions for the care of the poor.

PATHOLOGIC CONDITIONS OF THE PHARYNX AND CONTIGUOUS STRUCTURES DURING EARLY CHILDHOOD, PRIME FACTORS IN THE ETIOLOGY OF MALFORMED MAXILLÆ AND IRREGULAR TEETH, ETC.

Presented to the Section on Stomatology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY WILLIAM A. MILLS, D.D.S.
BALTIMORE, MD.

The physiologic functions of the nasal cavities are as follows: "They elevate the temperature of the inhaled air, give it moisture, and purify it by arresting all particles of dust and other substances which it may contain;" they act as resonance cavities for the voice and are also the seat of the sense of smell.

A professional experience of more than twenty-five years, has taught me that any inflammatory lesions—found in children between the ages of 4 and 12 years—which obstruct these natural conditions, are in the majority of cases, the chief agents in the causation of malformed jaws, and the consequent abnormal alignment of the teeth. (To the same cause can be attributed beaked or hooked noses, so often found in connection with these deformities.) I have reached this conclusion after many years of ceaseless endeavor to trace out cause and effect. Others may theorize differently, but theory alone will not stand, unless proven clinically correct.

I cite the following case in my practice:

A male child over 7 years old was brought to have a tooth filled, which was supposed to cause pain in the right ear and the right angle of the inferior maxilla.

The patient presented the following clinical conditions: Almost complete obstruction of the nasal cavities; face pale, anemic and haggard; features contracted at the angles of the jaws and beneath the malar processes, giving the characteristics of the mouth-breather or "dog-face," as Dr. Cathell terms them. I

found a small cavity in a molar tooth, which in no way could have caused the pain. This was filled but gave no relief. I depressed the tongue and examined the tonsils. These I found so greatly enlarged that they almost met at the median line. I was informed that deglutition was both difficult and painful. When the tongue was forced well down with a tongue depressor, quite a large quantity of yellow pus sprang from an unseen source in the right tonsil. On the removal of the depressor, the patient exclaimed, "My pain has gone!"

On examining the superior maxilla, I noticed a very perceptible contraction on both sides, anterior to the first permanent molar teeth, with a decided inclination of the roof of the mouth to become elevated.

I informed the aunt of the state of affairs, and that unless heroic measures were quickly taken for the child's relief, by a rhinologist, very serious consequences would be sure to follow.

Six months later the patient returned, and I was informed that notice had been taken of previous instructions and a specialist consulted the same day. He had removed some adenoid growths, and was still reducing the tonsils with the galvano-cautery. He was now a bright and rosy-faced boy, with normal respiration, and we found no signs of the former contraction of the jaws, or rising of the arch, all of their outlines being perfectly normal.

This particular case demonstrated that either the adenoid vegetations, or the enlarged and diseased tonsils, or both, were the prime factors in the causation, not only of the malformations of the maxillæ, but also the oral respiration.

If a correct diagnosis had not been made, and only palliative treatment been given, there is no doubt that a case of V- or saddle-shaped arch would have been developed, with irregular teeth as concomitants; especially as the patient's parents and grandparents are full-blooded Germans, and have large jaws and teeth.

I have often found similar conditions in young patients, whose parents thought so little of the matter that they deemed no treatment necessary, as the children never complained of pain; while others "made their own diagnosis, and treated for conditions which did not exist, being ignorant of all possible results." Thus, from time to time, the lesions were permitted to progress, until more acute symptoms developed, when the family physician was called; and as is often the case in such diseases, he failed to make a correct diagnosis, or give the proper treatment, and thinking the disturbance of no great importance only prescribed some simple wash or nasal douche, thus allowing inflammatory conditions, which could have been cured, to develop into more chronic forms with all their evil consequences.

The starting point in the majority of these cases, has its origin in some slight irritation of the mucous membranes of the throat, especially the tonsils. "It seems remarkable," says an authority, "that the fauces at this time of life, should be the seat of so many inflammatory processes."

To show with what indifference some practitioners treat such cases, I cite the following: A reputable physician, whose daughter, aged 14 years, has nasal catarrh, V-shaped arch, irregular teeth and an almost complete obstruction of the nasal cavities, when told that he should do something for her relief replied, "She will come around all right when she gets older;" and this seems to be the opinion with many general practitioners.

In conclusion, I would urge upon both medical and dental practitioners the importance of being ever on the alert to discover the first signs of any inflammatory manifestation in the throat or nasal cavities of children, as so many inflammatory disturbances are prone to develop in the respiratory passages, without in themselves showing any very acute symptoms, and

if permitted to continue without proper treatment, cause disease and malformations which in some cases defy all remedial agencies.

When a patient has a slight occasional cough or clearing of the throat, any peculiarity of intonation, huskiness of voice or nasal twang, an examination should be made to discover the cause, and when located, treatment given at once; and if oral respiration is fully established, some reputable specialist should be recommended, as he is better qualified to make a correct differential diagnosis, and prescribe the best remedies. I believe that if this is done, fewer cases of malformed maxillæ and irregular teeth will be found in the future than at present.

The following are a few replies to personal letters sent, asking for opinions as to the etiology of malformed maxillæ and irregular teeth.

Dr. John Nolan Mackensie, Johns Hopkins Hospital, says: "Rhinologists generally hold that the deformities in question are sometimes produced by nasal and post-nasal obstructions (deflection of the septum and adenoid growths being two conspicuous examples). Indeed, it has been shown experimentally that asymmetric conditions of the corresponding side of the cranium may be produced in young guinea-pigs by artificially occluding the nostril. Malnutrition must of course be at the bottom of the matter; due probably to defective blood supply, both in quantity and quality."

Dr. M. H. Cryer says: "It is my opinion, that an inflammation of the tonsil and surrounding tissue will cause tension of the palato-pharyngeal and palato-glossus muscles; if this be so, they would naturally pull the lateral portions of the arch downward and inward; especially is this the case with children when their bones are soft and yielding."

Dr. Harrison Allen says: "Probably the most important factor present is oral respiration. Disuse of important functions (instanced here by the nasal passages) invariably excite disturbance. No 'starvation' of the tissue is present in these cases as I understand them, nor is there disease, as the phrase is usually employed. I do not think undue pressure of the muscles against the jaws exists, nor are the jaws themselves weakened, except that they may be weakened by having their curves of normal action interfered with."

302 Dolphin Street.

HOLOCAIN HYDROCHLORID: SOME NOTES ON ITS USE IN OPHTHALMIC SURGERY.

BY J. WHITEFIELD SMITH, M.D.

Ex-Superintendent of the Illinois Asylum for Feeble-Minded Children;
Member of American Medical Association, Brainerd District
Medical Society and McLean County Medical Society.

BLOOMINGTON, ILL.

Up to the present time but little experiment has been made in the use of holocain in ophthalmic surgery. But from the clinical notes so far at hand, it would appear that it has some advantages and may prove to be a very useful drug in ophthalmic practice.

"Holocain is a synthetic substance having the composition of para-di-ethoxy-diphenyl-ethenyl-amidum, and the hydrochlorid has been used in a 1 per cent. solution as an anesthetic in ophthalmic practice, but on account of toxic properties is not recommended for hypodermic injection. Anesthesia is prompt and lasting, and is not accompanied by mydriasis or dis-

turbances of the accommodation" (*British Medical Journal*).

Dr. Robert Brudenell Carter of London contributed an article to the *Lancet* of May 29, in which he called attention to a paper read before the Belgian Academy of Medicine March 27, 1897, by Dr. Deneffe of Ghent, whose observations in the use of holocain were as follows: He said that "by applying a drop of a 1 per cent. solution to the eye three times, at intervals of fifteen seconds, complete anesthesia would be established in three minutes without pain, without change in the diameter of the superficial vessels, without dilatation of the pupil and without paralysis of the accommodation."

Dr. Carter from his own observation says: "I received a supply of holocain last week and used a 1 per cent. solution in the manner described by Dr. Deneffe, having first applied some to my own eye and found that it gave no pain. Four applications were made in the course of a minute and at the end of four minutes from the first of them I performed cataract extraction with iridectomy. The patient was unconscious of the first incision and was barely conscious of the iridectomy, not flinching or moving the eye. The section healed perfectly by first intention. A day or two later I used the same solution before slitting up the lachrymal canaliculus and rendered the operation absolutely painless. As asserted by Dr. Deneffe, there was no action upon either the conjunctival blood vessels, the pupil or the accommodation, and I can not but think that the new agent will be found highly useful in ophthalmic practice. The promptitude of its action is alone of no inconsiderable advantage."

Löwenstamm (*Therap. Monats.*, May, 1897) relates some further investigations into the use of holocain in 1 per cent. watery solutions in ophthalmic practice. It can not be employed subcutaneously, because its toxic action is considerably greater than cocain, and even in ophthalmic work it should be used in minimum doses. By applying a few drops anesthesia is produced in the eye in about ten minutes. The author has employed holocain in sixteen cases, of which seven were normal eyes, five were examples of foreign bodies, and four were operation cases. In one set of three cases, four drops were put into the eye and repeated in five minutes, when the anesthesia of the cornea and conjunctiva lasted on an average nineteen minutes. In six other cases the same quantity was used on three occasions at intervals of five minutes, and the anesthesia lasted on an average thirty minutes. A slight touch was felt before the lid reflex returned. In three cases four drops were applied on three occasions at intervals of two minutes, and here the anesthesia lasted on an average twenty-six minutes. This method has the advantage of requiring only a short time before the operation can be commenced. Often an increase in the anesthesia of the conjunctiva was noted after the second and third application, and where this did not occur a passing sensation of burning was experienced. The removal of the foreign body was accomplished in one eye eight minutes and in the other fifteen minutes after the second application, without the patient feeling anything. In two operations for squint lasting fifteen to twenty minutes two applications sufficed. As regards gradual action no difference was noted from cocain, but the tension of the bulb was not lessened, the cornea retained its luster and moistness and the pupil

was not dilated. No toxic effect was noticed and no change in the pulse or urine. Heinz allowed a 5 per cent. solution, and also the dry powder to be applied to his own eye, and no intoxication symptoms occurred. Perhaps holocain is less readily absorbed from the conjunctiva than cocain. Thus holocain is a prompt, pronounced and long-lasting anesthetic, with no unpleasant results. It should find a permanent place in ophthalmic practice. Boiling the solution is not requisite, as holocain possesses powerful disinfectant properties.

The only time I have seen it used was at the Royal London Ophthalmic Hospital (Moorfields) on June 25, 1897. The preparation used was a 1 per cent. aqueous solution. The case in which it was used was that of a senile cataract in a man about 60 years of age. Four or five drops were instilled into the eye at intervals of three or four minutes for a period of twenty minutes, then the patient was placed on the operating table and the eye carefully douched with a boracic acid solution. The anesthesia of the cornea and conjunctiva seemed perfect. Iridectomy was performed, apparently without pain. The only noticeable feature was a more profuse hemorrhage from the conjunctival vessels than is usually observed when we employ cocain. The wound healed promptly without subsequent pain or discomfort to the patient.

SOCIETY PROCEEDINGS.

Western Ophthalmological, Otological, Laryngological and Rhinological Association.

Abstract of the Proceedings of the Third Annual Meeting held in Chicago, April 7 and 8, 1898.

The Association met in the rooms of the Chicago Medical Society, and was called to order by the Chairman of the Committee of Arrangements, Dr. J. E. COLBURN of Chicago, who introduced Dr. F. HENROTIN, President of the Chicago Medical Society, who welcomed the Association on behalf of that Society and the local profession. He spoke of the necessity of modern specialists, and said that all recognized their value. He believes in societies and organizations. While there might be injustice done here and there, such societies would live and thrive and multiply.

Dr. A. ALT of St. Louis, responded to the Address of Welcome, and thanked Dr. Henrotin, in behalf of the Association for the very kind words with which he had welcomed the members on the occasion of their third yearly meeting.

The President of the Association, Dr. B. E. FRYER of Kansas City, was then presented and delivered a brief address in which he dwelt upon general matters pertaining to the work of the Association.

Dr. H. KNAPP of New York, delivered an address on

THE RADICAL TYMPANO MASTOID OPERATIONS.

Among the surgical procedures cultivated so successfully by otologists during the last decades, the so-called radical mastoid operation is the most important, but also the most difficult. The pioneer work of Troetsch, Schwartze, and others in this field was well known and fully appreciated, when Kuester in 1889 gave a new impetus to the further development of this branch of surgery by censuring aurists for operating too much in the dark. Zaufal and Stacke were the first prominently to take the hint in developing methods for making more extensive and thorough operations which have received the names of radical operations, comprising the removal in cases of chronic purulent otitis media, of everything diseased in the mastoid, attic, atrium, external meatus, and adjacent pneumatic spaces in one large cavity. Dr. Knapp described the performance of the operation with blackboard illustrations and presented numerous anatomic, both dry and wet, specimens. The methods of Zaufal and Stacke differed somewhat at first, but are at present virtually identical. The difference is that Zaufal begins the operation from the mastoid, and Stacke from the attic. The speaker dwelt on the precautions to be taken to avoid during the operation injury to the facial nerve and the horizontal semicircular, particularly by chiseling the mastoid

by broad vertical slices, layer by layer, finding first the antrum by measuring on a straight probe, first introduced through the posterior part of the auditory canal to the labyrinth wall of the tympanum, then down to the depth of the artificial canal, chiseling into the mastoid the length of both, and remembering that the aditus ad antrum is about at the level of the medial wall of the tympanum. To secure the position of the aditus the posterior wall of the ear canal should be sounded by a bent probe, either from the attic (Stacke) or from the mastoid (Zaufal), or from both, bearing in mind that the small canal mostly is not directed horizontally, but more or less ascending from the attic up and back. If probes are introduced both ways and left in position during the operation, we can with patience, cleanse the wound from blood, by good light recognize the parts clearly, and avoid injuring them both during the chiseling of the posterior wall of the osseous ear canal, and the lateral wall of the attic, a very important step in the radical operation, as also during the cleansing of the cavities with a sharp spoon.

The speaker described how to avoid injuring the dura mater in extending the operation into the posterior and middle fossae of the skull. The description and rules were illustrated by brief records of cases. The first was a smooth and temporarily successful operation, but death under fulminant symptoms occurred months later, apparently by the breaking of a cerebral abscess into the ventricles. In the second case, the facial nerve had been injured during the scraping; the partial facial paralysis disappeared completely in three months and the patient was doing well. The third case was a patient, 50 years of age, who had been operated on (the tympanum) by Professor Bruns of Tübingen, when she was 5 years old. Dr. Knapp removed the carious malleus five years ago; the otorrhea and very severe attacks of headaches and dizziness of late compelled her to seek the doctor. A radical operation cured the otorrhea and head symptoms. The patient said, "I feel like another person." The fourth case was that of a scrofulous child 2 years of age, operated on eighteen months ago. A most extensive operation was done, removing the carious and necrosed bone deep into the petrous bone. Recovery followed, leaving a deep, perfectly epidermized cavity behind the ear.

On motion of Dr. Alt a vote of thanks was extended to Dr. Knapp for his interesting address.

Dr. HUGH T. PATRICK of Chicago, followed with an "Address by Invitation," in which he dwelt upon the kinship of neurology, ophthalmology, otology, laryngology and rhinology.

Dr. ADOLPH ALT of St. Louis, read a paper entitled

RECENT RESEARCHES INTO THE HISTOPATHOLOGY OF TRACHOMA.

The frequency of this disease as well as its important position among the affections of the eye, must needs again arouse the desire to fathom its real cause and perhaps in this way to help in its prevention or cure. The author's researches in this direction date as far back as 1876, when he inoculated rabbits' eyes with trachoma. He was perfectly successful in producing a disease which apparently differed in no way from the real trachoma. However, this disappeared again in the course of from one to two weeks. He had some of the old specimens still and what he had succeeded in producing in the rabbit's conjunctiva differed histologically in no way from the disease in the human conjunctiva. Leber has had the same experience. After a lapse of years the author again took up the study of this subject on quite a considerable amount of material which he had gained by excising trachoma granules and cutting them into sections. His recent researches seem to confirm the previous ones. Notwithstanding the clinical difference between so-called follicular conjunctivitis and trachoma, the bodies which he has found and considers to be parasites in trachoma he has likewise always found in follicular conjunctivitis.

FIVE CASES OF PARINAUD'S CONJUNCTIVITIS.

A paper on this subject was read by Dr. H. GIFFORD of Omaha, Neb. He said the disease was first described by Parinaud in 1889, and hitherto nine cases of it have been described in France, while in Germany and Austria the same disease has been described by Goldzicher as lymphomatous conjunctivitis. It is characterized by rapid swelling of the lids with more or less mucopurulent discharge, and the development on the folds or tarsi or both of large rounded granulations which not infrequently are fungiform or polypoid in form. Between the granulations small conjunctival ulcers sometimes occur. Soon after, or in very rare cases, before the affection of the lids, the lymphatic glands of the neck and face on the affected side generally become swollen and tender to a very marked degree and suppuration not infrequently occurs. The disease is almost invariably one-sided, is apparently not contagious, and appears to undergo a spontaneous cure in the course of some months when

left to itself. Treatment in the worst cases affects the disease very slowly. The cases in which the tarsal surfaces are covered with granulations might be mistaken for very pronounced trachoma, while in those where ulcers of the folds surrounded by granulation tissue occur, the question of tuberculous conjunctivitis might be raised. The cornea is rarely, if ever, affected, and the subjective symptoms are comparatively slight. Parinaud has called the disease infectious conjunctivitis of animal origin, partly because some of the French cases were butchers or farmers, but the evidence on this point is not at all conclusive. Bacteriologic investigations as to its cause have been practically without positive results. Two of Gifford's cases were somewhat typical in so far as that in one of them the swelling of the lymphatic glands was confined to a row behind the sterno-mastoid muscle, while in the other the granulations were hardly as large as usual, the most prominent conjunctival feature being the presence of numerous ulcers mostly on the folds, but some of them on the tarsi and bulbar conjunctiva.

Dr. JAMES MOORES BALL of St. Louis, reported a case of "Quinin Blindness."

Dr. B. E. FRYER of Kansas City, read a paper on

THE ANTISEPTIC PREPARATION OF THE CONJUNCTIVA FOR CUTTING OPERATIONS OF THE EYEBALL.

He said the terms antiseptis and asepsis were rather carelessly interchanged by many practitioners, and this ought not to be. He insisted that in many instances surgeons did not, nor could not make a surface aseptic if they strictly included in the word asepsis not only the absence of septic material, but also the absence of the cause of sepsis, namely, pathogenic bacteria. He then showed how and why this was true. In antiseptic work on the conjunctiva only very weak solutions of sublimate or of iodid of mercury could be used. He maintained that a mercuric chlorid solution in the proportion of 1 to 6000 could be instilled in the conjunctival sac every day for weeks without any reaction being produced. The method of preparing the eye for a cutting operation upon it which he employs, is as follows: The face is thoroughly cleansed with soap and water, and then the orbital region is washed carefully with a carbolic acid solution 1 to 50. The eyelids and eyelashes at their roots are especially cleansed. The conjunctival sac is flushed carefully with 1 to 6000 sublimate solution, and a bichlorid gauze pad is put over and retained upon the eyelid, and it should extend over the brow and nose and down upon the temple and cheek. The dressing is changed daily, and daily the eyelids, brows and cheek are washed with carbolic acid solution and the gauze renewed. Latterly, in the beginning of the antiseptic preparation the speaker has instilled protargol solution 1 per cent., say for four or five days, and at the end of that time dropped in the mercuric chlorid solution. He finds in certain cases, especially in those patients who, from having prostatic trouble, and who void more or less pus with the urine, are very liable to infect the eye or have infected it. In such cases the protargol seems to stop the pus flow from the conjunctival sac readily and also removes the conjunctival congestion. These prostatic cases require greater care in preparation for eye operations than is usually given them even by those who believe in correct antiseptis. Many of the cases having pus cocci enter the conjunctiva, which cocci, while they have only an innocent surface lodgment, will there produce purulent destruction of the eye if admitted unrestrained on to the globe. By prolonged preparation and following the method he outlined, he thought oculists could restrain the pathogenic microbes in the conjunctiva as they are restrained in the derma, and sufficiently long to allow of healing before the restraint is removed by the germicide's final removal or elimination. He had microscopically demonstrated streptococci from the conjunctiva of eyes which were to be operated on, and which streptococci were so attenuated in power by the continued antiseptic preparation that no bad result followed the operation.

Of course the condition of the nares must be looked after, and he found that a weak solution of tincture of iodine in alboline, used as a spray, did effective work in attenuating microbes in the nasal cavities.

Dr. T. A. WOODRUFF read a paper on the

USE OF DR. DE ZENG'S REFRACTOMETER.

He compared the work of this instrument with the results arrived at by skiascopy and the test lenses. In every case the existing error of refraction was determined first with the refractometer and then by skiascopy and the test lenses, using each method independently of the other. All cases were worked out with the aid of either a 1 per cent. solution of atropin or homatropin and cocaine discs, the latter being used in the majority of instances. In some cases the amount of ametropia was determined first without the use of a cycloplegic, but where active accommodation was present the results obtained

were unsatisfactory. In about 50 per cent. of the cases he found the three methods agreed accurately, but in the balance, and particularly where an oblique astigmatism was present, it appeared impossible for the patient to decide between several axes. Skiascopy and the test lenses determined this much quicker and more acceptably. Dr. Woodruff drew the following conclusions: 1. That the refractometer is not a time-saver. 2. It is not always accurate in determining the amount and axis of astigmatism. 3. It is liable to produce an over rather than an under correction of astigmatism. 4. In old people, or where a cycloplegic is contraindicated, it will prove of assistance. 5. In myopia and hypermetropia it is most satisfactory in determining the full amount of the error under a cycloplegic. 6. It is expensive.

THE SCIENCE OF OPHTHALMOLOGY.

Dr. DUDLEY S. REYNOLDS of Louisville, Ky., read a paper on this subject. He said that the science of ophthalmology was in great danger of becoming tainted with loose methods of approximation. It was not to be wondered at that disappointment so frequently followed loose methods of analysis as to lead both patient and practitioner astray in searching for causes of pain and aches that refuse to yield to the supposed correction of errors of refraction. The decentered lens and the prism have seized upon the minds of some, whilst others have apparently gone daft in their search for ocular tendons to cut, or advance. An enthusiastic surgeon recently reported his achievements in the looping of ocular tendons with catgut ligatures. Dr. Stevens had created an apparently rational place for partial tenotomy: but it was not an uncommon occurrence to read of a dozen or more tenotomies, or advancements, of the tendon in a single eye. With the tendon looped, muscular co-ordination in the movement of the eyes might, in all probability, be expected to observe not alone the lateral, the vertical and the rotary movements, but like the famous gun with the curved barrel made to shoot bears behind trees, turned in all sorts of irregular directions to compensate for the eccentricities of opposing tendons.

A fine illustration of the results of painstaking practice was presented in the person of Mrs. T., aged 30 years, the wife of a prominent practitioner in Louisville. She came to him on Oct. 19, 1896, with divergent squint, photophobia, indistinct vision for distance, and total inability to read. She had suffered almost continuously with sick headache for a long time, and having been told that the ocular tendons must be advanced, her husband brought her to Dr. Reynolds, with the object of having whatever operation was found necessary done at once. On attempting to suspend the accommodation, he found he had unsteady muscular movement, the rotary muscles being in an almost constant state of activity. Without glasses she saw nothing; with the glasses she had, she saw 6-xxxvi Snellen, with the right eye, and 6-lx with the left eye. On examination of the glasses he found for the right eye she had -0.75 C. axis 170° \ominus -0.75 S. combined with a prism of 3° , base inward. In the left she had +2.00 C. axis 110° \ominus -3.50 S.

He prescribed homatropin drops to be instilled twice daily and directed smoked *coquilles* to be worn constantly, and no attempt to be made to see objects, excepting for purposes of going about. She went to the country and remained until April 30, 1897. When she returned the eyes were re-examined under homatropin, the use of which had been kept up during her entire absence. He found +1.00 axis 90° enabled the right eye to see -6-le Snellen; +2.00 C. axis 90° enabled the left eye to see -6-vi Snellen. These glasses were prescribed and she has worn them constantly ever since. She is fond of reading and having no children, has spent the past year in almost constant reading, with not more than two attacks of headache during the entire year, both of these clearly due to indigestion. The glasses she had formerly worn were chosen after a most painstaking and thorough analysis with the Javal-Schiotz ophthalmometer, the ophthalmoscope, and the Zeig refractometer, in the hands of an experienced practitioner.

The great point to be considered is that sufficient care should be taken to establish complete suspension of accommodation, and no final attempt to determine the state of refraction should be made for persons whose general health is such as to disqualify them from engaging in the normal use of the eyes. Proper discrimination in these matters, and a judicious course of constitutional treatment necessary to restore the patient's general health, are too often overlooked or neglected.

EXTRACTION OF IMMATURE SENILE CATARACT,

was the title of a paper by Dr. C. BARCK of St. Louis.

The current view of the necessity to wait for the so-called maturity of senile cataract needs to be modified. The lens after the age of 55 to 60 years is coherent enough, no matter how small the opacity, to admit of a complete and easy deliv-

ery, if the corneal and capsular sections are large enough. This opinion was first promulgated by Hirschberg of Berlin, in 1892, but bitterly opposed. The experience of the author, based upon dissections and operations, coincide with the teachings of Hirschberg. He reported ten cases of immature cataract in different stages, in each of which the operation was just as easy and complete as in mature ones. The conclusions of the paper are: 1. A senile lens, however small the opacity may be, is coherent enough to admit an easy extraction *in toto* by the proper method. 2. To wait for the so-called maturity is unnecessary. The operation can be performed as soon as the sight is impaired to such a degree that the vocation or comfort of the patient is interfered with. 3. All operative procedures for artificial ripening are unnecessary and are contraindicated, exposing the eye to a twofold danger.

Dr. A. E. PRINCE of Springfield, Ill., read a paper entitled "Ectropion of Lower Lid."

Dr. FRANK ALLPORT of Chicago contributed a paper entitled "A New Visual Chart for Schools for the Use of Teachers."

Dr. J. O. STILLSON of Indianapolis, Ind., read a paper entitled "Detachment of the Retina."

Dr. A. C. CORR of Carlinville, Ill., read a paper on

CHOROIDITIS AND CHORORETINITIS IN YOUNG PERSONS.

The essayist said that his own observations in practice had not been such as to enable him to agree with the ordinary teaching of the books and didactic instructions on the subject of choroiditis. From this source almost all cases of choroiditis that could not be unquestionably classed as rheumatic, gouty or traumatic, were at once considered as syphilitic, and this latter is confirmed and a positive diagnosis is made if any improvement or a favorable modification follows the use of mercury and iodid of potassium. It was this "trump" etiologic diagnosis that he wished to inveigh against. He gave a brief history of five cases selected as best illustrating choroiditis with retinal hyperemia as he sees it in private practice in young people, and without any possible syphilitic taint, approximately or remotely, and which he believes originates from excessive functional activity of the eyes.

Dr. L. R. CULBERTSON of Zanesville, Ohio, read a paper on "Rotation of the Axis of Astigmatism During Ophthalmometric Examination," and reported three cases.

Dr. A. R. AMOS of Des Moines, Iowa, read a paper entitled HEMIANOPSIA, FOLLOWED BY TOTAL LOSS OF VISION IN BOTH EYES, AS A RESULT OF UTERINE HEMORRHAGE FROM FIBROID TUMOR.

The case was that of a woman, aged 50 years, who had always enjoyed good health previous to the onset of a uterine hemorrhage which occurred nearly a year prior to any visual defect. Questioning the patient, and physical examination, revealed nothing of syphilis or of tuberculosis, and no inherited tendency to brain disease. The uterine function had always been satisfactorily performed until a year previously. During the period from the first hemorrhage to the complaint of visual defect her system had sustained frequent losses of blood from the uterus. Examination of central vision showed it to be above $20/30$ in both eyes. The perimeter revealed a full field on the left in both eyes, as well as good color sense, but visual perception from her right field was abolished. The pupil reflex and accommodative power were retained; ophthalmoscopic examination negative; no apparent paralyses of other nerves. The patient was irritable and fretful. The extreme pallor of the patient caused inquiries as to hemorrhage. Suspecting uterine tumor, the patient was at once referred to a surgeon with the assurance that the eye affection resulted from loss of blood. Accordingly, she was operated on by Dr. Etheridge of Chicago, shortly after which vision remained about the same as when the essayist had last seen the patient. Within three days following the operation she was again attacked with dizziness and became totally blind.

In closing, the author called attention to the following points: 1. The two lesions occurring at different periods of time and involving the same portion of each cerebral hemisphere, double homonymous lateral hemiopia. 2. While at first there was loss of central vision as well as peripheral, regeneration of the area connected with the macula lutea of one or both sides had taken place, leaving the other areas still implicated.

Dr. H. V. WÜRDEMANN of Milwaukee contributed a paper entitled "Multiple Angiosarcoma with Metastasis and Infiltration Into the Orbit."

At the evening session, Friday, Dr. ALT showed a specimen of adenoma of the ciliary process under the microscope, and also a slide showing the cells of trachoma.

Dr. CASEY A. WOOD of Chicago reported several interesting cases and exhibited the patients.

Dr. NORVAL H. PIERCE of Chicago reported a case of "Papilloma of the Larynx."

Other interesting cases were reported and the patients exhibited by Drs. W. F. COLEMAN, W. A. FISHER, THOMAS FAITH.

Dr. HOMER M. THOMAS exhibited a nebulizer for use in connection with the treatment of diseases of the respiratory passages.

Dr. C. D. WESCOTT of Chicago reported cases of non-pigmented sarcoma of the choroid; primary carcinoma of the conjunctiva; multiple lymphoid tumors of the orbits and subconjunctival dislocations of the crystalline lens.

Dr. EDWARD PYNCHON read a paper entitled

THE TECHNIQUE OF TYMPANIC INFLATION.

The philosophy of tympanic inflation is to accomplish either one or more of the following objects: To secure ventilation of the tympanum; to remove abnormal secretions or discharges; to restore the normal air pressure in the tympanum; to correct the engorgement of vessels which is due to rarefaction; to promote the absorption of inflammatory products; to push out the abnormally retracted drumhead; or to cause massage of the ossicles.

Middle ear inflation is indicated in chronic conditions of Eustachian tube catarrh; in chronic non-suppurative middle ear troubles; in suppurative conditions of the ear, whether acute or chronic, accompanied by perforation of the membrana tympani; and, when properly controlled, in conditions of acute inflammation of different degrees ranging to otitis media acuta.

In the use of compressed air not enough attention is given to the factor of dosage. Its physical properties may be varied as follows: 1, Variation in pressure; 2, intermittent flow with infrequent or rapid breaks; 3, continuous flow; 4, unmedicated air; 5, medicated vapors or nebulae; and 6, variations in temperature. With such a variety of physical properties it requires no argument to prove that in application its therapy can be proportionately extended.

In order to secure the required differences in pressure and flow, the writer showed an auxiliary air-tank of about five gallons capacity, which is provided with four valves and a meter, and, in order to suitably medicate the escaping air, the use of an inflator-inhaler and also of a nebulizer are advised. Some new methods of doing Politzerization are suggested in which, in suitable cases, as high as a sixty pound pressure is employed, when a lesser pressure fails to inflate.

The continuous air current, being used only in connection with the auscultation tube, is advised in chronic catarrhal conditions of the Eustachian tube, and in conditions of acute inflammation, and is employed only with the catheter, and with a pressure rarely exceeding twenty pounds. It consists of a flow without breaks for ten or fifteen seconds at a time, and can often be advantageously alternated with Politzerization. For a variety of reasons given, the use of the Politzer air-bag is decried except as a makeshift in bedside practice.

Dr. E. O. SISSON, of Keokuk, Iowa, read a paper on

MASTOIDITIS.

He confined himself to the etiology and pathology of the subject. As regards the etiology, statistics go to show that the most common cause of acute inflammation in this region is an extension of a similar process from the middle ear, the primary lesion being either acute or chronic in character. Primary mastoiditis, although uncommon, is occasionally seen, and may follow an exposure to cold or traumatism, or may be a manifestation of a tubercular or specific diathesis. But the most common cause is chronic suppurative inflammation of the middle ear.

The author drew the following conclusions from observations of the etiology and pathology of the affection: 1. The large percentage of cases of mastoiditis are the direct result of chronic purulent otitis media, but that they are not produced in proportion to the frequency of the latter, and therefore, there must be some existing condition or conditions that exert an influence in this direction. 2. That in the light of anatomic observation the pathologic conditions are not necessarily the same in any two cases, and that such observations tend to more firmly establish the fact that an inflammation of the mastoid process is a condition fraught with great danger to life.

A REVIEW OF THE PATHOLOGIC CONDITIONS AFFECTING THE LINGUAL TONSIL,

was presented by Dr. E. C. ELLETT, of Memphis.

After noting the early history of the study of this tissue, Ellett described this organ as the anterior portion of oropharyngeal lymphoid ring, lying behind the circumvallate papillae, in the pre-epiglottic space, continued upward laterally to almost

merge into the faucial tonsils. It is divided into two lobes by the median glosso-epiglottic ligament, and is composed of separate lymph follicles. Its function is, according to Somers, to prevent lodgment of food, to moisten food with its mucous glands, and to assist, by moisture, the gustatory function of the back of the tongue. Derangements of this organ are common, but frequently overlooked. The author considered: Acute inflammation, and abscess; chronic inflammation, including hypertrophy and varix; specific inflammations, and new growths.

Acute inflammation presents much the same symptoms as other acute faucial inflammations, with the addition of frequent edema of the glottis and epiglottis, and severe cough. The treatment consists in demulcents and astringents, with poultices, and internally salol, preceded by a purgative.

Chronic inflammation manifests itself as hypertrophy, often accompanied by varix of the lateral lingual veins. The mirror is necessary to make the diagnosis, though rarely the glands can be seen, when enlarged, by direct inspection. The symptoms to which this condition gives rise are a sensation of a foreign body in the throat, a feeling of constriction at the upper border of the thyroid cartilage, reflex cough, a constant desire to clear the throat, quick laryngeal fatigue and hemorrhage. The condition is especially prone to attack women, and is commonly seen in persons from 20 to 30 years of age. In addition to the correction of any dyscrasia, the treatment consists in removal of the mass by cutting, caustics, or by application of iodine. Special tonsillotomes have been devised for the purpose, though the author removed the glands in one case with a straight instrument. The snare may be used, but the galvanocautery is probably the best instrument.

Of the specific inflammations, tuberculosis has not been noted, while syphilis is not unusual, especially in the secondary stage, with faucial and pharyngeal implications.

New growths are rare. Cysts, fibrosarcoma and angioma have been seen.

Dr. JOSEPH A. MULLEN of Houston, Texas, contributed a paper on

THE USE OF SUPRARENAL CAPSULE EXTRACT IN MINOR EYE SURGERY.

The objects to be attained in using suprarenal capsule extract are to prevent pain and hemorrhage in minor operations on the eye and its appendages. Its effects are the result of its physiologic action upon the small arterioles, a vasoconstricting action, thereby retaining the cocaine solution within the tissue. The latter solution precedes the use of the extract. Its use seems to furnish primary healing of the tissues and also to modify post-operative swelling. The intraocular tunics are reduced to a state of ischemia by its contractile power, but accommodation and the pupils remain unaffected. The solution is made by dissolving five grains in 5j of cold saturated boric acid. It keeps very poorly and should be prepared fresh for each operation. The solution is not at all irritating but rather imparts a cooling sensation to the conjunctival membrane. It is always used five to ten minutes after a 5 per cent. solution of cocaine has been instilled. The author has used the extract in removing pterygium adhesions of lids to eyeball; slitting canaliculus and cutting structures of nasal duct, etc.

THE SUBMERGED TONSIL.

Dr. EDWIN PYNCHON of Chicago, read a paper on this subject, in which he called attention to the frequently met-with condition of faucial fullness wherein, when the patient is caused to gag, the wholly or partially concealed tonsil is thereby protruded from between the pillars to which it is generally attached. Follicles, from which exude cheesy masses which contain pyogenic germs, pus cells and other deleterious matter, the continuous swallowing of which tends to impair the health, are thus exposed. Associated with this condition of the tonsils will be found postnasal catarrh, chronic pharyngitis, and at times stomachal or ear trouble, as well as a susceptibility to hoarseness and in some cases to acute attacks of tonsillitis. The submersion is partially due to tonsil hypertrophy and in part to pillar hypertrophy.

In the treatment of this condition thorough ablation is recommended by a process described as "electrocautery dissection," to which the writer called the attention of the profession by a paper in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, Nov. 22, 1890, but since which time the operation has been somewhat modified by dividing the attack upon each tonsil in two steps, which are taken ten days or two weeks apart. In this way, as compared with the former method of removing the entire tonsil at one operation, the annoyance of the operation and the danger of hemorrhage have both been materially reduced. The various steps of the operation and after-treatment were fully described and the instruments employed

shown. This operation, while originally designed for adults only, is now employed with children of 7 or 8 years of age, by increasing the number of steps and doing less at each sitting, though the attacks are made more frequently.

The results obtained by this method were reported as being highly satisfactory in all ways and a permanent cure follows of those symptoms depending upon the condition of tonsil being considered, and also in case of vocalists an improvement of the singing voice. A strong argument was made in favor of the most radical treatment, as when the tonsils are diseased, as they most assuredly are in the condition described, then their functional capacity is irrevocably destroyed and, therefore, in accordance with the principles of latter-day surgery the only possible indication may be for total ablation.

(To be continued.)

SELECTIONS.

The Forcible Correction of the Deformity in Pott's Disease.—The forcible rectification of the deformity of the spine in Pott's disease is a subject which in France and Germany is awakening the widest interest. It has hardly found its way into American or English literature yet to any extent (JOURNAL XXIX, 745; XXX, 709) partly because it is all so recent and partly because each one hesitates to approach the subject in a critical way on the facts so far presented. The method is essentially one which requires the lapse of a considerable amount of time for the estimation of its real value. The method proposed is this: the patient is anesthetized, and lying on his face is forcibly pulled upon by one assistant on each arm and leg while the surgeon leaning over him presses down upon the deformity until it yields or he sees fit to desist. The patient is then laid on his back on a padded board or enveloped in plaster from his head to his pelvis, for some months. It is claimed by some writers that permanent improvement and almost cure of the deformity may be obtained in this way. We are taught, and analogy would lead us to believe, that traumatism to bones or joints affected by tuberculous disease renders the tissues more vulnerable to the inroads of the bacillus and the general system more likely to be affected by generalization of the tuberculosis. The forcible tearing of tuberculous bone tissue has been again and again demonstrated to be risky and attended often by meningitis or general tuberculosis. For example, in twenty-seven cases of the forcible rectification of the deformity in hip disease recently reported by Raymond Sainton, five developed fatal meningitis within two or three months of operation. Objections on practical and theoretic grounds instantly occur: 1. Pott's disease is a tuberculosis of bone of the bodies of the vertebrae, and the deformity is secondary and is an incident. It has been regarded as in a measure conservative and as nature's preliminary to arresting the disease. The essential is vertebral tuberculosis, not deformity of the spine. Were the treatment proposed the eradication of the disease, it would place it on a different plane; but the measure deals only with a symptom and a result which is of itself distressing, and sometimes disabling but which is on the whole fairly well controlled by early and efficient treatment. Other things being equal it is, of course, most desirable to improve or obliterate the deformity; but the essential of any rational treatment is first to cure the disease. 2. The question of the occurrence of bony repair to fill in the gap caused by the tearing apart of the bodies of the vertebrae is, of course, an essential one. If there is to be no bony repair the operation is useless. It is asserted (Ménard) that in Pott's disease bony repair occurs, not in the bodies of the vertebral column, but at the sides and back. But Regnault quotes a specimen in the Musée Dupuytren, where a gap exists in a diseased column, but the column is stable. One must remember, as shown by experiments on the cadaver, after rectification, that the gap to be filled may measure two to six centimeters or more. No pathologic evidence beyond the specimen of Regnault has been adduced to show that bony repair of the vertebral column of a character likely

to support weight is likely to occur. Chipault, the modern originator of the method of forcible correction, and the predecessor of Calot, who seems to have reaped the glory, lays much stress upon ligature of the spinous processes in Pott's disease: not only does he ligature them after forcible correction, but as a routine method of treatment of Pott's disease in children even before the occurrence of deformity he advises "ligature by a silver wire of the spinous apophyses corresponding to the diseased region, a ligature followed by immobilization." A stout silver wire is twisted from one spinous process to another, so as to embrace and steady the whole area affected. After forcible correction Chipault has either wired the spinous processes together or has clamped the laminae together by an appliance somewhat like Malgaigne's patella hooks. A column supported in this way has, he says, double the strength of the intact column. Upon this ligature Chipault insists as one of the essentials, not only of forcible correction but of all treatment of Pott's disease in the active stage. Relapse, without this is, he says, most likely to occur. Calot claims that bony tissue fills up the gap caused by the separation of the vertebral surfaces on the ground that radiographs show it, instancing one where there were seen two beams of bone stretched across the gap after an interval of three and a half months, eight to ten millimeters thick and two centimeters long. Again, he says that where the operation is done in two stages, weeks or months apart, distinct snaps of bony tissue are felt at the second redressement. Ducroquet has brought forward radiographs which are said to show bony repair of the gap in the vertebral bodies. The reproductions of these radiographs in his (Calot) article is far from satisfying one that these statements are warranted by them. The general opinion is that the question of bony repair of the gap in the vertebrae must be regarded for the present as wholly *sub judice*. Such a process is not in line with the general behavior of bone when affected by tuberculosis and disturbed by traumatism. It cannot be dismissed as impossible, nor can it yet be accepted as proved to have occurred after the forcible correction in Pott's disease. If bony repair of the gap does not occur the operation is of questionable ultimate utility unless the spinous processes are wired, as advised by Chipault. Among those who have reported relapses are Pean, Phocas, Tausch and Lorenz and Vincent. 3. One would suppose that such operations must be attended by risk to life, but the reported casualties are surprisingly few. The cord and membranes in experiments on the cadaver have not shown signs of injury. Ménard in correcting the deformity on the cadaver ruptured a prevertebral abscess which would have found its way into the mediastinum during life. Lorenz speaks of a case where an operation was undertaken to arrest a threatened paraplegia; permanent paralysis immediately followed of a severe type. In addition to these dangers, hemorrhage, opening up of tuberculous foci, injury to intrathoracic vessels, etc., are advanced as theoretic possibilities. It is obvious that in old cases where union has occurred fracture of the spine will result from attempts at correction sufficiently forcible. Such an accident is reported by Malherbe, where a deformity has existed for eight years in a patient twelve and a half years old. The results quoted are surprisingly good. Calot comes first with 204 forcible corrections. There were no accidents, no deaths on the table. Two children died inside of three months, one of broncho-pneumonia and one of meningitis. In eight cases of paralysis, six cures resulted within eight days. In one case partial paralysis came on some days after correction. Twenty of his operated cases walk already; but his end results are too recent to be worthy of serious consideration. He states that the X ray shows the process of repair to be finished five to ten months after operation, sometimes requiring fifteen months. The criticism of Calot's figures made by M. Monod seems reasonable. In a critical report of the papers of Chipault, Calot and Ménard he made the statement that the statistics of Calot

were too good, and for that reason would not carry weight. On the other hand, it must be remembered that Calot operates at Berck-sur-Mer under the most favorable hygienic conditions; and, as one of his critics said, could venture on things unsafe in cities. Chipault has operated for four years. He says there are many relapses, and that unless the apophyses are fastened together, practically all will relapse.

In England, Jones and Tubbey have done eleven reductions. In six they obtained immediate and complete rectifications, in five only partial. Lorenz has been already quoted with one case of paralysis, and at the same time relapse of the deformity. Jonnesco reported three deaths in thirteen reductions, one from chloroform, one death unexplained by autopsy forty-eight hours after reduction, and one death from bronchopneumonia after eight days. Most of the series of cases are, however, much more favorable. As far as figures go to show immediate dangers, one must admit that if representative cases are reported, the immediate results are altogether more favorable than could have been predicted on theoretic grounds. The limit of applicability is indefinite. Cases of three and four years' duration have been often corrected, and adults and children have yielded equally good results. Calot makes in doubtful cases traction of 40 to 80 kilograms; and if there is no yielding he stops. Very old cases are obviously unfit for such operation. In two such cases, however, Calot has done a cuneiform resection of the posterior parts of the vertebrae and has thus accomplished reduction. This method, of course, diminishes the chest capacity markedly. The technique is simple, the patient lies prone and is pulled apart by strong assistants pulling on the arms and legs so as to distract the vertebrae at the seat of disease. Jeannel of Toulouse, and Vulpis of Heidelberg, use pulleys and bands for distraction in place of assistants, and the latter advocates suspension by the heels as the most available position for correction, and the application of the jacket. Calot advises as the first step of the operation the removal of the spinous processes of the diseased vertebrae through a longitudinal incision which is at once sewed up. This is advocated on the ground that pressure can then be made by the flat of the hand in rectifying the deformity, which is more accurate than pressure on each side of the spines; and it is said that sloughs are much less likely to form under the jacket. On the other hand, it is claimed that the removal of the spinous processes weakens the already diseased and unstable column. Traction of 20 to 80 kilos is made by Calot, according to circumstances, and then the surgeon standing over the patient presses downward on the boss with short jerks, exerting a pressure from 15 to 40 kilos. The deformity generally yields with a succession of snaps or suddenly and easily. The patient is then held with the spine overextended while a plaster cuirass is applied reaching from the top of the head to below the pelvis. This is changed every three or four months. Sloughs are likely to occur, especially on the occiput and over the boss. Recumbency of some months is advised, and the indication, according to Calot, for the upright position unsupported is afforded by the X-ray, which shows the formation of bone. All this seems to the American reader very indefinite and vague. Chipault lays the patient, after the operation, on an elaborately arranged board for hyperextending the spine.

Such is the literature as it stands. Lorenz and Ménard are the chief critics; Chipault, the real reviver of the method, is conservative and cautious; Monod is judicial and sceptic; the majority are enthusiastic. Theoretic objections are all very well; but every new operative method has had to meet them at the outset and either disprove them or be itself discredited. The operation attacks, not Pott's disease, but the deformity of Pott's disease, which is not the worst feature of the affection. It expects of tuberculosis of bone a reparative power and a behavior in general which it does not possess in general. It is not apparently attended with much risk, but its real

utility in *permanently* maintaining the improved position is yet to be proved. The operation is apparently not particularly dangerous. One need not use in all cases an obviously unreasonable amount of force, as advocated by Calot, but several gentle rectifications may follow each other. Paralysis may often be cured; the deformity may be largely corrected, temporarily at least, in recent cases; and in view of the decidedly unsatisfactory status of the present treatment of Pott's disease, the method is bound to be used, probably abused, advocated and decried until finally it finds its real level and is estimated at its true value. What that real value is no one can tell until much time has elapsed, time enough to show ultimate results. There has been yet no interval for the discussion of anything more than immediate results regarded in the light of the slow progress of tuberculosis of bone. Neither is it possible to say yet just which cases are best suited to this treatment. They must obviously be recent cases, that is, cases without ankylosis; and adults and children are apparently equally amenable. Beyond this nothing definite can be said. The method is of value in one way, even if time should prove it in every other to be worthless, which is altogether unlikely. It has shown us that an ambulatory apparatus can be applied which shall hold straight even a vertebral column where the bodies of the vertebrae do not exist but where they only bound a gap. But this apparatus must include the head and shoulders. If this turns us aside temporarily from our routine of braces and jackets to remember that body weight can be supported elsewhere than on the vertebral bodies, if we are only willing to use sufficient apparatus, the method of Calot, or rather Hippocrates, will have helped conservative methods and given new energy to the efforts to prevent deformity.—Lovett in *Boston Medical and Surgical Journal*, March 10.

We notice also in the *Centralbl. f. Chir.* of March 26, a later communication on the subject from F. Lange, who recommends a cast after forcible rectification, which only extends from the clavicular to the inguinal region, as he has found the Calot corset not only clumsy, but almost sure to produce various disturbances in the circulation of the neck and head. The cast is applied especially tight in front over the upper half of the sternum and the front edge of the ilium, and behind, at the region of the lower ribs, with a large opening cut out over the abdomen. It holds the spine in perfect lordosis without interfering with the arms or out-of-door life of the child. He adds that physicians now should never allow spondylitis to progress to actual deformity, and maintains that all the benefit of reduction, except in extreme cases, is in straightening the healthy parts around the boss. This paragibbous rectification, as he calls it, while free from all the dangers of the actual gibbus reduction, is equally effective and can be performed without narcosis, which is especially dangerous in these operations. He even asserts that in many cases with perfectly satisfactory results, in which it was supposed the gibbus had been reduced nothing but a paragibbous reduction had been accomplished after all, which could have been performed fully as well without the narcosis.

Spanish Destroyers and Torpedo Boats Destined for Cuba.—The *Scientific American* of March 19, represented an illustration of several of the destroyers, torpedo boats and torpedo gun-boats destined for service in Cuban waters. We quote: The first division, which include the torpedo boat destroyers *Pluton*, *Terror* and *Furor*, and the torpedo boats *Rayo*, *Halcon* and *Azor*, is under the command of Fernando Villamil. The second division will consist of the torpedo boat destroyers *Osado*, *Audaz* and *Proserpina* and the torpedo boats *Ariete*, *Habana* and *Barcelo*. These boats are the pick of the Spanish torpedo flotilla. They present the very latest developments in torpedo boat design, and one of them, the *Ariete*, was at one

time the most notable vessel of its kind in the world. This little craft is a torpedo boat proper as distinguished from the later destroyers. She was built to the order of the Spanish government in 1887, by Thornycroft of London, and on her trial trip broke all existing records by maintaining a speed of 26.1 knots per hour. This was considered phenomenal at the time, and remained for several years the record speed for a steam vessel; indeed, it was not until such large vessels as the *Havock* and *Hornet* made their appearance in 1893 that her performance was surpassed. The *Ariete* is 147½ feet long and of 97 tons displacement. She has 1600 horse power and carries an armature of four 3 pound rapid-fire guns. She is provided with two torpedo tubes. The *Rayo* is a sister boat to the *Ariete*, was also built by Thornycroft, but is credited with half a knot less speed. Of the other three torpedo boats, the *Azor* and the *Halcon* are larger boats of 108 tons. They have the same horse power but two knots less speed. Their armament is the same, but they carry an additional torpedo tube. The *Habana* was built by Thornycroft in 1887. She is a small boat of 59 tons displacement, has two torpedo tubes and has 21.3 knots speed. The *Barcelo* was built by Normand, well known as the inventor of the boiler which bears his name and by the successful torpedo craft which he has turned out. She is of 66 tons displacement and 19½ knots speed and carries two torpedo discharges. All of these boats are designated as first-class and are comparable in speed and equipment with similar boats in other navies. The strength of this flotilla lies in its brand new destroyers. The destroyer is an enlarged torpedo boat provided with sufficient size and power to enable it to keep the sea with a fighting fleet, something that the torpedo boat can not do. In the course of the English naval maneuvers it was soon discovered that the high speed of the torpedo boat was strictly a fair weather speed, and naval constructors realized that greater weight, size and power were necessary to render these little craft serviceable anywhere outside of sheltered waters. At the same time the enormous increase in the torpedo boat flotillas of other European navies necessitated some defensive action against them, and it was resolved to build a fleet of vessels of from 300 to 400 tons displacement, armed with powerful guns which would be capable of running down and destroying torpedo craft. Of the three which are in active service, the *Furor* and *Terror* were launched in 1896. They are 220 feet long, 22 feet beam and 5½ feet draught, with a displacement of 380 tons and a speed of 28 knots. They have twin engines of 6000 horse power and bunker capacity for 100 tons of coal. There are two torpedo tubes and the complement of men is 67. The armament is heavy, too heavy according to the ideas of our own designers, consisting of two 12-pounder rapid-fire guns, two 6-pounders and two 1-pounders. The 12 pounder fires a 3 inch shell weighing twelve pounds with a velocity of 2200 feet a second, which is capable of penetrating eight inches of iron at the muzzle; so that it can be seen that one of these boats could annihilate a torpedo boat as soon as it had run up within range. Of the four other destroyers, one, the *Pluton*, is already in service, and the other three, the *Audaz*, the *Osado* and the *Proserpina*, will sail at an early date. These four are identical in all respects and they have the characteristic of being considerably the largest destroyers in the world, being over 100 tons greater displacement than the largest English boats of this type. Their speed, however, is not so great by two knots. The particulars are as follows: Length, 225 feet; beam, 22½ feet; draught, 5.8 feet; displacement, 400 tons; speed, 30 knots; horse power, 7500; coal capacity, 100 tons; and complement of men 70. They carry two torpedo discharges and their armament is identical with that of the *Furor* class. In bringing these boats over the Atlantic everything will be done to guard against accident and disablement in heavy weather, especially in the case of the smaller boats. The guns will be unshipped to reduce top weight and provide additional coal-carrying capacity for the long journey.

PRACTICAL NOTES.

Salve for Acute Articular Rheumatism.—Sodium salicylate, 30 grams; iodoform, 10 grams; vaselin, 100 grams; extract of hyoscyamus, 5 grams. For external use.—*Nouv. Remèdes*, February 24.

Lupus Cured with Inoculations of Blood from Erysipelas Patches in Another Patient.—A severe case of chronic lupus of the face, closing the mouth so that speaking was impossible and no solid could be taken, the eyelids also swollen together, is reported.

Antipyrin in Sciatica.—If injections of antipyrin do not always relieve sciatica it is because they are not made deep enough, so as to bring the analgesic actually into contact with the nerve trunk.—Kuhn in *Sem. Méd.*, March 10.

Radiocoodenser.—A cone-shaped lead tube to conduct the rays to the screen is the latest improvement in radiography. The entire strength of the rays is thus concentrated.—*Bull. de l'Acad. de Méd.*, March 15.

Spray for Dry Pharyngitis.—Phenic acid, 4 grams; tincture of iodine, 50 centigrams; tincture of aloes, 40 centigrams; tincture of opium, 10 drops. Glycerin q. s. to make 30 grams.—*Nouv. Remèdes*, February 24.

Nervous Grip.—G. Baccelli recommends the following powders for nervous grip with hyperthermia: Quinin salicylate, 20 centigrams; phenacetin, 15 centigrams; camphor, 2 centigrams; for one powder. Take two to six powders during the twenty-four hours.—*Sem. Méd.*, March 10.

The Favorable Action of Convallaria Majalis in dropsy of renal or hepatic origin has been announced by Janowski, who prescribes it in an infusion of 4 grams of the plant to 180 grams of water, a tablespoonful every two hours, changing later to a 1 to 12 alcoholic tincture, of which 45 to 80 drops are taken during the day. It also favorably influences the diuresis in hepatic cirrhosis.—*Sem. Méd.*, March 10.

Albumin Tannate as a Preventive of Diarrhea.—L. Rosmheld has found that the diarrhea which so frequently accompanies the use of cod-liver oil or calomel, can be prevented by administering 2 to 4 grams of albumin tannate during the day. Fifty rachitic children thus treated were enabled to continue taking the cod-liver oil for months, while diarrhea occurred at once if the tannate was suspended.—*Nouv. Remèdes*, February 24.

Effect of Diphtheria Antitoxin on the Kidneys.—Rojanski has been studying the effect of small preventive doses (2 to 3 c.c.) on the action of the kidneys in seventy-three cases, and finds that it has no deleterious influence. No traces of albumin were discovered in the urine. He also reports a case of severe scarlet fever and nephritis in which diphtheria supervened, and larger doses of the antitoxin (10 c.c.) were administered. The diphtheria was arrested at once, and the nephritis also seemed to be favorably affected and retrogressed, although more slowly.—*Revue de Chir.* from *Botkine's Gazette*, 1896, No 36.

Inflammation of the Sinuses of the Face are so frequent that they are found in 20 per cent. of the necropsies, and in 90 per cent. of those preceded by grip. V. Boland recommends remaining in bed if there is much reaction. Sudation with pilocarpin will sometimes afford much relief. He advises Moure's inhalations of the following: Add to a hot infusion of aromatic herbs a teaspoonful of the following: Pure alcohol, 150 grams; menthol, 5 grams; eucalyptol, 5 grams; oil of gaultheria, 5 drops; inhale for five minutes four times a day. Lermoyer recommends the following: Pure alcohol, 100 grams; menthol, 5 grams; add a tablespoonful to a bowl of hot water and inhale by the nose through a funnel for five minutes, every two hours. The Politzer douche cleanses the sinus in some cases. The contents of the sinus can also be aspirated out sometimes by deep inspirations, with the mouth and nose tightly closed.—*Gaz. Méd. de Liège*, March 17.

No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, APRIL 23, 1898.

THE PHYSIOLOGIC EFFECTS OF EXTRACTS OF
THE HYPOPHYSIS CEREBRI AND INFUNDIBULAR BODY.

The hypophysis cerebri, or pituitary body, is currently described as being composed of two lobes; the anterior, larger lobe, is embryologically described as arising from the epithelium of the mouth cavity, its glandular structure resembling in many respects the structure of the thyroid gland. It is stated by HALLER¹ that it possesses an incomplete system of ducts that open between the meninges. In a recent article, W. H. HOWELL² maintains that, properly speaking, the term hypophysis cerebri should be restricted to this lobe. This significance is now given the term by most morphologic writers, but human anatomy commonly includes the so-called posterior lobe as well.

The posterior lobe lies upon and is partially covered in by the hypophysis proper, and it will be recalled that it is connected by a stalk to the infundibulum, and that embryologically it is regarded as an outgrowth of this part of the brain. For these reasons it would indeed seem quite desirable to speak of this posterior lobe as the infundibular body.

This body is small as compared with the hypophysis proper. The only satisfactory study of its histology is that by BERKLEY,³ who used the Golgi method, and reports a complicated and curious structure. There are many nerve cells, a cortical layer of ependymal cells, neuroglia tissue, peculiar structures resembling nerve-end-organs, and also a quantity of epithelial cells arranged in part to form tubes enclosing glandular-

like vesicles, some of which contain a colloid material. Now, this rather complicated make-up would indicate that the infundibular body is not merely a rudimentary organ, but that the glandular tissue may possess a secretory activity of some kind.

Following the recent modern methods of studying the physiologic actions of the so-called ductless glands, the investigators have also attempted to study the action of the extracts of the hypophysis cerebri. SZYMONOWICZ⁴ states that in experiments of this kind made upon dogs, there was a fall of blood pressure and a quickening of the heart beat; in other words, just the opposite of the phenomena observed after the injection of the adrenal extract. OLIVER and SCHAEFER⁵ obtained different results. Their extracts of the hypophysis caused a marked rise of blood pressure with increased force of the heart beat, results which resemble the action of the adrenal extract, with these differences, however, that there was in the case of the pituitary extracts no slowing of the heart beat.

The somewhat contradictory results obtained by these investigators led HOWELL to make further experiments of the same nature, but with this very important modification, viz.: that in his experiments extracts were made both of the hypophysis cerebri, or anterior lobe, and of the infundibular body, and the effects of these were tested separately by injection into the circulation of anesthetized dogs. In most cases glycerin extracts were made from the fresh tissue; the two lobes were first separated and then rubbed to a creamy pulp with a small quantity of glycerin. The mixture was then allowed to stand for several hours, when it was diluted with a few cubic centimeters of normal saline solution and filtered.

In most of the experiments the gland from the sheep was used, because it is larger than that of the ordinary laboratory animals, as for instance the dog, and also because it was readily obtained at the slaughter houses and easily removed from the skull. The facts obtained by injection of the two different extracts were as follows:

Extracts of the hypophysis alone caused little or no recognizable change in the blood pressure or heart rate, and HOWELL concluded that upon the whole the extracts of this body have no definite effect upon the circulatory or respiratory organs.

With the extracts of the infundibular body the results were marked and quite constant. The main effect was a pronounced slowing of the heart but with an increase in the blood pressure. When the vagi were cut there was a prolonged rise in the blood pressure, but a slower and stronger heart beat. As compared with the adrenal extracts the effect of the extract of the infundibular body is characterized by its long duration. The pressure rises more slowly, remains above the normal for a longer time, and sinks

⁵ Journal of Physiology, 1895.

gradually. If repeated injections are made the effects may be much less marked or may fail altogether, the results depending in this respect upon the time between the injections and also upon the amount of extract used. The loss of reaction following repeated injections is much more marked than in the case of the adrenal extract. It would seem as though the organs affected acquired an immunity from the active substance of the extract, but how long this immunity may last HOWELL did not attempt to determine. Neither has he yet attempted to determine what the nature of this remarkable substance is.

The fact that the physiologic reaction of the extracts of the infundibular body differ so very markedly from those caused by extracts of the hypophysis cerebri, in connection with the differences of structure, differences of origin, show that that they are physiologically and anatomically independent structures. The marked influences of extracts of the infundibular body suggest that this organ may produce a secretion of great importance to the functional activity of the organs of circulation. And certainly this tends to disprove the view that the infundibular body is merely a functionless rudiment.

THE BACILLUS MUCOSUS CAPSULATUS (BACILLUS OF FRIEDLAENDER).

Since the first description by FRIEDLAENDER in 1883, and by WEICHSELBAUM three years later, of an organism which was first called a coccus (pneumococcus of FRIEDLAENDER) and later regarded as a bacillus, occurring in acute fibrinous or croupous pneumonia, this bacillus has been found by many observers in various inflammatory processes in the lungs and other organs.

As specific characteristics of this organism were pointed out, its raised mucus-like growth on agar and blood serum, its nail-shaped growth on gelatin, its yellowish-gray growth with gas formation on potato, its failure to coagulate milk, absence of indol reaction, and decolorization by Gram's method of staining; it was generally found to be constantly pathogenic for mice, variably so for guinea pigs (fatal in about one-half of the cases), rabbits and pigeons, and finally its polymorphism and capsule formation were regarded as quite specific. From time to time bacilli differing in some respects from the foregoing description have been met with in pneumonia and other affections, especially in inflammations of the middle ear and upper air-passages, as well as in the peritoneum, liver, kidneys and bladder, and lately also in the accessory sinuses of the nose. For these reasons there have often appeared in recent literature descriptions of a new bacillus pathogenic for man. Most of the authors have pointed out the striking similarity between these various organisms and the bacillus of FRIEDLAENDER. More or less striking differences in growth and other characteristics have nevertheless been assigned as sufficient reasons for establishing new classes.

The bacillus of FRIEDLAENDER, often called the pneumo-bacillus or capsule bacillus, is stated by HONL to occur in from 5.5 to 8 or 10 per cent. of the cases of croupous pneumonia, and more frequently, alone or with other bacteria, in bronchopneumonia. It is not uncommon in the usual complications of these affections. It has also been found alone, or with other bacteria, in inflammations in the liver, kidney, bile passages, lachrymal gland, in the nose in rhinoscleroma, in ozena, in the accessory sinuses in the nose, and in hemorrhagic septicemia of the new-born. It has also been demonstrated in the saliva of healthy mouths, in healthy noses, in the ground, dust and air.

FRICKE has been able to collect twenty-two bacilli from the literature which resemble the bacilli of FRIEDLAENDER. He points out the many identical features and includes them in one single group, with that of FRIEDLAENDER as the type. He proposes as a name for this group the *Bacillus Mucosus Capsulatus*. He has found such organisms thirteen times, often mixed with pus cocci, in the tympanic cavities of thirty-two cases of otitis media, in one case in the antrum of Highmore, in ulcerative endocarditis, in the stools in seven cases of gastro-enteritis. He makes the differences in the pathogenic actions of these bacilli the basis for two groups. In the first group he places those bacilli that kill white mice after subcutaneous inoculation and which have none, or only a passive pathogenic action, when inoculated into the abdominal cavity of guinea pigs and rabbits. In group two are included those forms that are not pathogenic for mice on subcutaneous inoculation. Most of these were pathogenic for guinea pigs.

FRICKE insists that the so-called ozena bacillus is identical with the *bacillus pneumoniae* of FRIEDLAENDER. FRAENKEL, PAULSEN and ABEL have all described a mucus-like encapsulated bacillus in connection with ozena. Very recently W. T. HOWARD, Jr.,¹ of Cleveland, Ohio, from whose article the above facts are abstracted, has briefly described ten cases in which he encountered the *bacillus mucosus capsulatus*. These cases varied very much as to the nature of the lesions. Four concerned purulent discharges from empyema of the antra or frontal sinuses; one was a case of puerperal septicemia; another was a case of peritonitis and pyelitis after obstruction to urinary outflow from enlarged prostate. Another was a case of chronic peritonitis in a girl eight years of age, the peritoneal cavity containing a large amount of thick, creamy, tenacious pus, which on microscopic examination showed pleomorphic capsulated bacilli, and the culture showed a bacillus identical with the bacillus of FRIEDLAENDER. Another case was one of acute croupous pneumonia, with general febrinopurulent peritonitis. The bacilli found in these cases did not agree with each other in all respects, differing

¹ Phila. Med. Jour., Feb. 19, 1898.

especially in the varying amounts of gas production and varying in pathogenesis for guinea pigs and rabbits. HOWARD concludes that this bacillus is much more commonly associated with acute and chronic infectious processes than is generally believed.

JOSEPH J. CURRY² considers the *bacillus capsulatus* with especial reference to its connection with acute lobar pneumonia. He found it as a pure or mixed infection in twelve cases of various kinds including acute fibrinous pneumonia, acute endocarditis, otitis media, diphtheria and tonsillitis. The connection of the *bacillus capsulatus* with acute croupous pneumonia is especially interesting. The routine bacteriologic examinations of pneumonia as carried out in the Boston City Hospital, for instance, have shown that it is invariably due to the *micrococcus lanceolatus*. One of the cases referred to by CURRY throws considerable light on the cases of pneumonia which have been considered as due to the capsule bacillus in so far as it demonstrates that the growth of this bacillus may be and usually is so profuse as to obscure the growth of the diplococcus; examination of the sections from the lung in this case by the Gram stain, as well as with methylene blue, showed that the bacilli were, as would be expected, decolorized by Gram's method, while the diplococci were present in large numbers in the alveoli and in the pleural exudation; with the methylene blue stain the bacilli were found quite numerous, chiefly in the bronchi.

SCIOLISM AND SUPERSTITION.

Some two or three years ago an essayist in a popular review, under the title of "The Recrudescence of Superstition," tried to prove that with all our boasted progress, there was evidence that the world was going backward in at least one respect—that instead of becoming more emancipated from degrading superstitions mankind was getting to be more and more their slave, and adopting ideas and practices that better fitted the middle or the so-called dark ages than the present time. It was, as one might naturally suppose, a partial view and not a judicial statement of facts; the author focused his attention on certain facts that have existed from all time and ignored the real prevailing conditions about him. Men have always been more or less superstitious, and no amount of culture can entirely make them anything else, and in the uncultured the grossest beliefs have at all ages, not excepting our own, found their supporters. Human credulity is an indefinite quantity and it would be a rash man who would venture to set its limits.

No one has a better opportunity to observe this fact than the physician, one might say perhaps "the regular physician," for there is altogether too large a contingent of those whom the public regards as physicians, who live and thrive by encouraging some form or

other of misdirected medical belief, and who, if honest, can hardly be considered as capable of taking, so to speak, an external and impartial view of such delusions. There are even "regular" physicians who from some peculiarity of mental constitution, are incapable of distinguishing between science and pseudo-science, and are therefore sometimes carried away by pretentious theories supported only by a confused and confusing jargon of misused technicalities, and it may be the revival of some antiquated but still somewhat specious delusion in physics or philosophy. With the laity, medicine, in its popular acceptance, is still to a large extent what it was in MAGENDIE's time, "the grand idol of human credulity"; there is hardly anything so absurd as not to command some one's faith and domestic practice. Christian science, which is apparently supplanting homeopathy as a female cult, osteopathy, and all the other "pathies" and "isms" that are rampant at the present time, are sufficient evidence of this fact.

The JOURNAL not long since editorially noticed the appearance in a respectable medical publication of the lucubrations of a Washington pseudo-scientist who, in despite of physical laws, claimed to be able to cut visible sections of less than one-hundredth of a micrometer, and to infinitely increase the magnifying power of microscopes and telescopes, so that, judging from his pretensions, one might assume that the infinitely distant and the infinitely little would be yet revealed from the satellites of the fixed stars on the one hand to the vortex gyrations of the ultimate atoms on the other. This passed for science sufficiently to be noticed without specially adverse comment in popular scientific serials, so that possibly one should not too severely criticise the medical editor who passed the contribution as suitable for publication. But when we see articles in what we may call at least a semi-medical journal, supporting "psychometry," the juggling of the clairvoyant, and that gypsy specialty, palmistry, as having not merely a real value and truth, but as supported by physiologic and anatomic facts, we can reasonably wish, for the credit of our profession, which in a way is the sufferer, that the editor had been more discriminating. The discussion that once ran through a leading foreign medical journal on the deleterious influence of the accidental presence of a menstruating woman during the process of curing hams, was, in its way, much more respectable; it gave only the individual expressions of honest ignorance and superstition, while such publications as are here referred to are ignorance and superstition invested in a pretentious sciolism, which adds a sort of element of fraud, unconscious though it may be, to the delusion.

All men, learned or not, may be assumed to be still somewhat superstitious, or to have at least the possibility of it in their composition. There is enough

² The Journal of the Boston Society of Medical Sciences, March, 1898.

of the mysterious and incomprehensible about us to almost justify it in the ignorant, and no one should know this better than the medical man. He can while honestly admitting the limitations of his own knowledge, be philosophically tolerant of the weaknesses of others. It is harder, however, to be tolerant with those who, adopting the superstitions of the ignorant or denying their own limitations, endeavor to bolster up their delusions with their half-digested acquisitions of scientific terminology and theories.

THE RELATION OF THE PHYSICIAN TO THE PURITY OF DRUGS.

The old saying "none are so blind that they will not see," is well exemplified by the lack of regard shown by some physicians concerning the conditions as to purity and excellence of the medicines which they prescribe. The surgeon usually has sufficient acumen to recognize the fact that his instruments must be thoroughly reliable if creditable results are to be reached and after some years of experience he learns to regard a certain manufacturer's products reliable and usually purchases his supplies from that source until some accident reveals to him that his confidence has been misplaced. Not so with the physician who writes a prescription for his patient and sends him out to get it filled by whom and where he will, or who for motives of economy purchases for his own dispensing cheap pharmaceutic products which must needs be uncertain in their effect. Can anything be more suicidal from the point of view of the man who desires to be ranked as a successful practitioner, and can anything be more futile than his attempt to treat serious maladies with preparations which are to good drugs what a jack-knife is to a well made tenotome.

Our attention has been called to this fact so often that we are apt to regard a failure to produce an expected effect rather as the result of some such fault than as an evidence of our having been mistaken as to the diagnosis of the disease or the remedy needed. Some years ago a drug firm in the Atlantic States purchased a large amount of impaired and damaged pharmaceutic products of all sorts and then marketed them by sending travelers to the office of hundreds of physicians who for the sake of saving a few cents on every thousand pills, or tablets, not only impaired their professional reputation by their use but were guilty of a breach of trust in that they in one sense innocently used feeble remedies in serious maladies when their patients placed their confidence in the physician doing the best for them that was possible.

Since that time other evidences of a similar lack of the ability to perceive what is for our best interests have been made manifest and time after time physicians fail to get effects because the original drug is poor or the dispenser careless in the preparation of the finished product.

A visit to the store of any wholesale drug house will reveal various grades of almost every drug. The best grades are at a high price, the poorer ones at much less cost. The druggist with the theory of "save a penny, lose a pound," purchases the cheaper grades and is fortunate if his medical and lay patrons do not discover him.

Finally, there exist men who, with more of an eye to the dollar than to humanity, deliberately take it upon themselves to adulterate pure drugs and thereby cheat the sick not only of their money but perhaps of their lives.

This editorial is not the place to discuss the well-worn theme of substituting one article for that ordered, on the ground that it is "just as good," bad as the results of such action may be. It is the place, however, for us to insist on the physician forearming himself against such evils as may impair his career and cause his patients suffering. With the large manufacturing chemists, who by buying enormous quantities of crude drugs can get pure ones at as small a price as the individual druggist can buy poor drugs and who place upon the market accurately prepared, chemically assayed or physiologically tested products there is no reason why every physician and patient should not use the best the world affords.

That the views just expressed are correct is evidenced by the following facts derived from the *London Pharmaceutical Journal* concerning adulterations in England and from the *Pharmaceutical Era* as to adulterations discovered by the Massachusetts Board of Health. The first journal tells us that: the Local Government has published its twenty-sixth annual report, according to which there were 1380 samples of drugs analyzed by public authority in 1896, of which 156, or 11.3 per cent., were found to be adulterated. The percentage for the past four years has been about 11 per cent., so that last year was not much above the average. Of niter (? spirit of nitrous ether), 51 out of 196 samples were condemned; of rhubarb (? tincture), 22 out of 128; and of ipecacuanha wine, 10 out of 29. The purity of beeswax was well looked after during the year, 10 out of 46 samples being condemned. One was a mixture of about 30 parts of resin to 70 of ceresin, while another contained 75 per cent. of paraffin and only 25 per cent. of genuine beeswax.

As the *Pharmaceutical Journal* well says: "The only way to extinguish adulteration, is to render it unprofitable; and it is observed in the annual report just quoted, that many local authorities have represented the inadequate fines repeatedly inflicted by magistrates to be an encouragement to adulteration."

In Massachusetts the principle articles found to be adulterated or below the standard were ether, alcohol, ammonia water and chlorin water, distilled water (in this article the solids varied from 0 to 73 per 100,000

parts), extracts of licorice and nux vomica, powdered opium, compound spirits of ether, spirits of nitrous ether, whisky, tincture of iodine, syrup, tincture of opium, mercurial ointment, white and red wine.

On the selfish basis of professional success, on the sacred basis of the care of human life, with all that its loss means, let us see to it that our medicines are as pure and capable for the combatting of disease as are the appliances used by the surgeon, who is better off in that he can watch their effects every second and see the area he is operating upon.

THE COMING WAR IN CUBA.

The all-absorbing topic of the week among all classes of people is the question of war. Naturally the physicians are as much interested as any particular class, and much speculation is being indulged in, especially by medical officers of the National Guard, as to the climate of Cuba with reference to service on that island.

In regard to the danger from yellow fever, it is proper to say that the Surgeon-General of the Army, Surgeon-General STERNBERG, is probably as familiar with the conditions as any one in the United States, and it is safe to trust his advice in all those matters. It is, however, not out of place to state that the island is a mountainous one, and if the troops are kept out of the cities as far as possible there will be but little danger of contracting yellow fever.

The boiling of all water the exact composition of which is unknown, is imperative. Besides this, a handy individual pocket filter can be improvised by using a soft rubber funnel provided with a tube; inside of the rubber funnel place one or two layers, as may be desired, of filtering paper (a small package of which should be provided in each knapsack, to be used sparingly as the occasion requires), hold the funnel high, and pour the water through it into the canteen. When not in use the funnel is rolled up and put in any handy pocket, or the haversack.

In regard to the general hospital and field hospitals, there is no tropical country which affords more sites for general hospitals in the mountains than the Island of Cuba, and the fatuity of the Spaniards in placing so many sick soldiers in the infected military hospital on the shore of the stagnant arm of the Bay of Havana, is a melancholy spectacle of incompetent administration. Even at Mariano, but a few miles from Havana, it is well known that yellow fever is infrequent, and it is vastly more healthy than the city. The mountain range of Cuba extends along the whole island, commencing with the sharp peak Pico Turquino 8240 feet high, and extending as a backbone along the island. The hills near Matanzas rise to an elevation of nearly 1200 to 1300 feet, and there is no question that the interior of the Island of Cuba is as healthy as any country in the tropics. If proper precautions be

taken, there is no question but immunity from yellow fever can be secured by the rigid observation of sanitary regulations, and prompt isolation of any infected case among the troops that may arise through carelessness or faulty hygiene.

MILITARY SURGEONS.

The meeting of the Military Surgeons at Kansas City in May next may be interfered with owing to the fact that so many of the officers will be otherwise engaged than attending medical conventions. The same reasons interfere with the meeting of the American Surgical Association at New Orleans this week, but to a less degree.

CORRESPONDENCE.

The Serum Treatment of Tuberculosis.

ST. LOUIS, Mo., April 11, 1898.

To the Editor:—In Dr. Waxham's letter on the above subject in your issue of April 9, Dr. Waxham asks, and the question is a fair one, why no criticism was made on the reports of the serum treatment in two papers in your issue of February 5, "in which sixteen cases were reported, of which fourteen were chronic cases, having existed from one to eleven years," and suggests that it may have been because those reports were more favorable.

It has been the practice of Messrs. Jno. T. Milliken & Co., on receiving first applications for serum, to caution the prospective users as to the limits within which claim is made for its usefulness. Dr. Waxham was himself so cautioned, for I find in my letter to him of Nov. 13, 1897, the following words: "Of course I need hardly say that its chief use lies in the early stages of tuberculosis. It can scarcely be expected to renovate organs which are in a state of absolute structural disorganization." To a man of Dr. Waxham's professional standing any more explicit statement seemed uncalled for.

That being the rule, there was no occasion to criticize the reports of February 5, to which Dr. Waxham refers; nor would any criticism have been called for upon Dr. Waxham's report, had he not made the assertion therein that "the cases reported would seem to be fair ones with which to judge the value of the treatment." In regard to the claims made for antiphthisic serum, that statement left no alternative but to combat it. . .

Dr. Waxham is, no doubt unintentionally, scarcely fair when he says that Dr. Millican "decides" that all, except possibly one or two cases, were cases of mixed infections. My words were: "It is a fair inference from the clinical reports, notwithstanding the absence of temperature records, that there was mixed infections, etc."

It is neither "proven" nor "admitted" that the serum treatment is a "failure" in long-standing chronic cases of tuberculosis. There are many such on record as either cured or markedly improved thereby, some of which are recorded in the two papers of February 5 referred to. At the same time they are at present regarded as exceptional, and the caution is given that good results ought not to be anticipated in such cases. The question is one of degree, and only to be solved by cumulative evidence of which Dr. Waxham's report will ultimately form part.

Dr. Waxham tells us that "Early cases invariably recover." If that be so, where do the chronic cases come from? . . . Dr. Waxham's concluding advice is certainly sound. The

essence of general medicine lies in giving every therapeutic arrow its place in the therapeutic quiver. "Specialism in Therapeutics" has been that cause of many useful adjuncts being long retarded in their claim for public recognition, e.g., hydrotherapy, electricity, etc. The quacks who claimed to treat all diseases, and all cases thereof, by these methods alone, are responsible for the long delay in their acceptance as very valuable therapeutic measures. The true physician does not seek to establish any "universal or exclusive rule" of treatment, but employs all or any methods, collectively or severally, which according to his experience and what he knows of the experience of others, appear to be suited to the individual case before him. But when a new method is on its trial, it is not fair to discredit it by the assertion that cases clearly outside the claims made for its recognition, are "fair ones with which to judge the value of the treatment."

Were the fourteen cases of February 5 and Dr. Waxham's ten to be taken alone as representing all that is to be said for and against serum treatment in "long standing cases of chronic tuberculosis," it seems to me that the balance of evidence would be against Dr. Waxham's assertion that serum therapy has been proven to be a "failure" in such cases, though neither could its success be held to be conspicuous. But, as a matter of fact, neither Dr. Waxham's ten cases against, nor the fourteen more or less favorable to, its results in chronic cases, are the evidence of its value in such cases, but parts only of the evidence on which the future verdict will be rendered; and as such are equally valuable, and equally welcomed by honest investigators.

Yours very truly,

KENNETH W. MILLICAN, M.D.

Suggestions Concerning Publication of Association Papers.

To the Editor:—The approaching meeting of the AMERICAN MEDICAL ASSOCIATION, at which, by the way, I propose to present two papers, moves me to write to you on the subject of your methods (rules?) of publication, which I do principally from the standpoint of the reader, for I have no grievance to air, all my former contributions to your columns having been printed in the most satisfactory manner. But the present state of your columns, now, in April, publishing many valuable contributions made to the ASSOCIATION last June, and several extremely prolonged communications that have appeared during the year and which have probably been a cause of this undue postponement, together with the preliminary programs already announced for the coming meeting, give rise to the serious apprehension that if the latter are carried out and you are favored with other voluntary contributions extending over months, you will be completely swamped during the next year in a mass of material of very varying degrees of usefulness and interest. Therefore, it seems to me that now, or early in the meeting, would be a proper time to take, before it could be considered to have any personal bearing, a new departure, in the interest of overburdened readers and impatient contributors.

There are certain articles, learned, excellently written, and within their limits useful, which possess but comparatively little interest for the general reader. To be specific, such are translations of historic works, carried out with true German thoroughness and corresponding dullness, which would be excellent for the scholarly surgeon to have in his library but which have no proper place in the pages of anything called a journal.

A year or two ago the proceedings of the ———al Society filled your columns for months with a mass of details, important no doubt to those interested, but conveying little or no meaning, if read, to the vast majority of your readers. An abstract of those papers and discussions in the tenth part of

the space would have been of infinitely more use, and would have had twenty readers to every one who gave up the original in despair. The histories of the specialties and the Sections of the ASSOCIATION giving, for instance, the names of officers and papers read for each year of their existence, might better be published in the organs of the appropriate specialties. It is not inspiring to read in the spring of 1898 that in June, 1897, Dr. ——— said that the Section on ———ology was organized with Dr. ———, Chairman, and Dr. ———, Secretary, and that Dr. ——— read a most able and interesting paper, and so on, for each year of its existence, closing with the statement that the Section has made a most notable contribution to the knowledge of the subject throughout the world, and undoubtedly under the able leadership of the speaker's accomplished successor will still pursue the path of glory and science.

It must be acknowledged, also, that there are some papers consisting of such helter-skelter facts, real or supposed, mixed up with much vague speculation and very likely moral and ethic reflections that would not bear editing, which would spoil their flavor, often unique and racy, but which should not be allowed to take up space unless they have the literary and numerous qualities making them enjoyable and an agreeable relief from severer labors.

Then come the compilations, which, if well done, are often the most useful of all for the busy man, but which may be fit subjects for revision.

I wish to make two alternative propositions: 1. The publication of a daily edition of the JOURNAL during the session, containing an abstract of everything and as many of the general addresses in full as there may be room for, and this edition to be continued long enough afterward to publish everything in full or at least long enough to let the editor see daylight through his mass of copy before the end of the year, with room for something else.

Under the present arrangement the authors are liable to find themselves in the predicament of Mr. Ibsen, who alone, with the exception of the Good Lord, so reticent of important human secrets, knew what he meant when he wrote "Peer Gynt," but has long since forgotten. From such an edition the reader could take what he likes, as we do out of the Sunday newspapers.

2. Subjection of all papers read before the ASSOCIATION, or the more or less affiliated Societies which meet about the same time, excepting always the addresses of Presidents of Societies and the three general addresses, but not excepting the addressee of Chairmen of Sections, to a sufficiently large committee. They should act promptly, as far as possible, during the meetings through subcommittees in each Section, and complete their work within a month, at the end of which authors should be notified of their decision. They should report that a given paper should be published either: 1. In full. 2. In full, omitting the historic introduction. 3. In extracts. 4. In abstract. 5. By title.

If reported in any of these ways, except the first, the author should have the paper or any portions of it omitted, placed at his own disposal to publish as he might see fit, and he should also, if possible, prepare the extracts or abstract desired, within space limits, to be assigned by the committee, when he is notified of their decision. This committee should include two or three members from each Section who could do the bulk of the work during the meeting or within a day, to be afterward completed by correspondence. Such a committee would relieve the JOURNAL of a great deal of dead-weight and the editor of the exceedingly unpleasant task of telling his confrères that their contributions are not available. It would also be possible for such a committee to act by correspondence throughout the year and pass at least upon the longer contributions such as might extend over many numbers.

I am very respectfully,

**

Licenses to Practice.

HYDE PARK, VT., April 23, 1898.

To the Editor:—In your issue of the 9th inst. I notice a correction sent in by Dr. Mailhouse calling your attention to the fact that Connecticut now requires an examination for license to practice medicine. I give below a complete list of States now requiring an examination for admission to practice, having obtained the same at considerable trouble and expense for my work on medical education and registration. They are as follows: Alabama, Arizona, Connecticut, Delaware, District of Columbia, Florida, Georgia, Cherokee Nation Indian Territory, (Iowa after Jan. 1, 1899), Louisiana, Maine, Maryland, Massachusetts, Minnesota, Mississippi, Montana, New Hampshire, New Jersey, New York, North Carolina, North Dakota, Oregon, Pennsylvania, South Carolina, Tennessee, (Texas in dispute), Utah, Virginia, Washington and West Virginia.

Idaho had a very good law passed a year ago which has since been declared unconstitutional owing to some irregularity in the Senate records; consequently it will have to be classed in the list of six States which have practically no medical practice laws, viz., Vermont, Michigan, Kansas, Wyoming, Nevada and Idaho.

Ohio and Rhode Island have taken decided steps to prevent medical schools locating in towns of less than 50,000 inhabitants.

Twenty-seven States besides the District of Columbia, Cherokee Nation Indian Territory, and Arizona now require examination for license to practice, of which number seventeen require both diploma and an examination. Some of the States not requiring an examination, as well as some that do, have very stringent rules governing the recognition of diplomas.

A four years' course of lectures, with a very considerable amount of preliminary education as a condition of recognition of diplomas, is demanded by something over a dozen States, in response to which 117 of the 155 medical schools in this country now require attendance on four annual courses of lectures, of which number twenty-seven require attendance on sessions of eight months, and ten of nine months each year. May each and every State soon require an adequate preliminary training and annual sessions of at least eight months instead of six, as some of the second- or third-rate schools will not fall into line until they are driven to it.

Very truly yours,

WILLIAM T. SLAYTON, M.D.

Author "Medical Education and Registration United States and Canada."

Eustrongylus Gigas.

CENTERBURG, OHIO, April 11, 1898.

To the Editor:—On page 717 of the JOURNAL an article appears on the subject of "Eustrongylus Gigas," by Dr. G. W. Morehouse. Having been a neighbor for almost twenty years, and for a number of years the family physician of the patient mentioned, I presume some correction in regard to Dr. M.'s statements might be in order from me. Mr. H. (the patient) is a rather robust man in appearance to the person who would stop with a superficial survey, but to the physician who examines the case will come a revelation, for the man has fatty degeneration and the usual train of general symptoms that follow in the wake of such conditions.

He was a cavalryman in the late war, and since the war has been a merchant until a year ago. Prominent among the symptoms of the above named condition is the heart trouble, on which he was pensioned some years ago. I have watched with interest the case for at least fifteen years, many times during that period I have been called on to relieve him of attacks that came on suddenly, both of heart complication as well as for severe attacks of renal colic. I have helped to take him home many times from his place of business under such

circumstances. On March 10, 1896 (date given by Dr. Morehouse), I was attending the case and had been with the patient nearly all night. He was suffering from renal colic; the next day he passed several small calculi, and in a few days was attending to his business affairs as usual. Now note the difference in the records which I have before me, and those narrated in the JOURNAL by Dr. Morehouse.

Fully twelve months after the attack I have just recorded Mr. H. had another severe renal colic followed by quite a hemorrhage, the quantity of blood passed was estimated at fully a pint or more.

A day or two later he passed in the urinal a worm-like specimen about six inches long; with it was more or less debris, consisting of small coagula, etc. He brought the specimen to me, which I examined carefully by shredding it on glass and magnifying. I pronounced it blood fibrin in the form of a cast of the ureter. Several of these passed during the week or two following, none more than seven inches long. As soon as the tendency to hemorrhage ceased no more of the so-called parasites developed.

Mr. H. carried some of these specimens to my friend Dr. F. C. Larimore of Mt. Vernon, who upon examination decided that it was blood deprived largely of its coloring matter by having been held in the ureter. The patient being a man who liked notoriety, carried a few sample "worms" in a bottle to show his friends, and in this way wonderful reports of the case were given out over the neighborhood, and the exaggerated statements of the man himself I think, in a measure, led Dr. Morehouse, who lives in a village a few miles away, to make the report as he did.

Mr. H. as is usual in such cases, drifted into the hands of a specialist who bears a reputation for not being very guarded in his opinions, and who is governed in the treatment of his cases more by the color and quantity of a man's money than anything else. This physician treated him for a time for Bright's disease and later chanced it on "Eustrongylus Gigas."

The difference in opinion naturally prompted me to defend my position. I sent a specimen to a friend of mine in New York (a gentleman who is known to Dr. Morehouse, at least by reputation) who is an eminent pathologist, and his opinion coincides with Dr. Larimore's and mine. His idea was that one or more sharp calculi were in the kidney, and the irritation from their presence provoked the hemorrhage and a temporarily obstructed ureter held the blood until a cast was formed, and as the constriction gave way the worm-like cast passed into the bladder and later out by way of the urethra with the urine. The shreds were only fragmentary blood coagula, etc.

With this explanation I hope those who read the former article, and may read this, will be able to draw some rational conclusions. The case furnishes at least an object lesson for the general practitioner. The patient's health remains much the same as it has been for several years. I see him every day as one of his neighbors. By way of conclusion I might say this, as Dr. Morehouse had never treated the case he reported, and even the specimen of urine he says he examined was voided long after the "passing of the worms" I think his diagnosis has been too hasty and faulty in the extreme.

ROBERT C. M. LEWIS, M.D.

Rumination in Man.

ASHTON, R. I., April 14, 1898.

To the Editor:—I was much interested in Dr. Sinkler's paper on "Merycism or Rumination in Man," published in your issue of the 9th inst., as I recollect that when a young man, say from 18 to 25 years of age, I frequently, at long intervals, used to return my food, especially after a hearty meal when accompanied or more often followed by the use of wine or other alcoholic beverage, and finding it rather agreeable, remasticated and restored it to the stomach.

I agree with Dr. Sinkler that rumination is not the result of indigestion but of improper mastication, at least in cases where, as in my own, the food returned is sweet and pleasant, and he is undoubtedly correct in his opinion that it passes out of the stomach and ceases to be returned to the mouth as soon as it becomes fit for intestinal absorption.

N. O'D. PARKS, M.D.

Gynecology and Gynecologists in Paris.

(Concluded from page 928.)

PARIS, March 1898.

Dr. Championnière, though perhaps known more widely as a general surgeon than as a gynecologist, does considerable of gynecologic surgery. In doing his vaginal hysterectomies he makes his incision with a thermocautery instead of with the knife and scissors. One peculiarity about all his work is that he washes every cut surface, of whatever kind, with a 2.5 per cent. solution of carbolic acid. He uses this fluid in the peritoneal cavity with a rashness that seems astounding to one who has been taught that its toxic influence is to be feared. He is a perfect enthusiast on this subject and says that in his abdominal work, where he encounters pus sacs and the like, his results are just as good as when these complications are absent, all of which he attributes to his free use of his one to forty solution of carbolic acid. He never, under any circumstances, drains the peritoneal cavity, except in the cases where he has wounded the coats of an intestine and where he fears he may have a fecal fistula follow his operation.

For many years he did his work at the St. Louis in a couple of old wooden pavilions with wooden floors, where all the surroundings would appear to be unfavorable. He is now at the Bonjon and does his abdominal work in an isolated brick pavilion, the inside finish of which from an aseptic point of view seems to be perfect.

I remarked to him: "You can do better work here and have better results than you could at your old quarters at the St. Louis." He replied: "On the contrary, my results have never been as good here as they were at my old rickety barrack at my old home. Surroundings play no rôle in this matter. This thing of having every one who witnesses an abdominal operation put on an outside sterilized garment is all a fad. If the dirt and microbes do not touch my patient, the instruments or the dressings do not fear them. My results here are not as good as at the St. Louis, because I have not been able to organize my help here as well as I had at my old stand."

About one-half of the surgeons in Paris use ether, and the other half chloroform. Dr. Championnière says he used ether for two years and then abandoned it for chloroform, and avers that he has seen patients die six months after an operation from chest trouble which he attributed to ether.

Many gynecologists here in Paris claim that the removal of the uterus with the annexes prevent those nervous phenomena that follow the removal of the latter leaving the uterus intact. Championnière denies this absolutely, and avers that the presence or absence of the uterus after the tubes and ovaries are removed, plays no rôle in the matter whatever.

Monsieur Tuffier, at the Pitié, is a fine operator and has lately introduced an innovation in the way of a hemostatic that I think will be new to most of the readers of this article. With this new instrument, which consists of a huge clamp nearly one foot long, the clamp end of which is about one-half inch wide, and which is closed by a kind of jack-screw arrangement at its distal extremity, he is able, after applying it for a few seconds to the broad ligament and uterine arteries, to remove it and no bleeding follow. Thus he does his vaginal hysterectomies without having a single clamp or a single ligature on any blood vessel when he has completed his operation. In his abdominal hysterectomies he only puts on two ligatures, and

those on the uterine arteries where the tissues are too short and unyielding to apply his clamp. If this manner of controlling hemorrhage proves a success, it will save these patients a great deal of discomfort, as well as lessen the liability of infection in this class of cases.

The Doctor banishes from his surgical paraphernalia all antiseptics. He cleanses his hands first with soap and water and then washes them in 95 per cent. alcohol. He uses aseptic gauze for all sponging and dressing purposes.

Dr. Bouilly at the Cochin does an immense amount of gynecologic surgery. He must be very popular with his fellow practitioners here in Paris, for I find that a large number of them bring their patients to him to be operated on. When Dr. Apostoli encounters a case of uterine fibroid that his electric treatment will not benefit, he brings it to Dr. Bouilly for an operation. After seeing considerable of the Doctor I am inclined to attribute his popularity to the fact that he talks but little, a virtue that many of us do not possess.

Of the many questions that are still unsettled, and with regard to which we seem to be still at sea, that of the indications for the drainage of the abdominal cavity after a laparotomy stands out as a most prominent one. The question not only as to whether or not you should drain at all but the material that you should use for your drainage, is still a bone of contention among our best operators. The glass tube that is still used by some surgeons, Pozzi and many others say, does not drain, while the gauze that one sees used so often here in Paris Bantock says is a horrid thing to put into the peritoneal cavity, as its use is likely to be followed by adhesions that will leave your patient in a wretched condition and perhaps require a second operation to break up the peritoneal adhesions that your gauze has produced. Championnière, as I have said, never drains, while Bouilly drains lavishly, using a large perforated rubber tube that he cuts off level with his abdominal wound.

Dr. Bouilly is extremely painstaking in his antisepsis and he as well as Richelot and many others in the French capital, adopt the following plan for disinfecting their hands as well as the field of operation: 1, Wash in soap, using brush freely; 2, wash in a 5 per cent. solution of permanganate of potassium; 3, decolorize the washing in a solution of bisulphate of soda; 4, wash in a 1 to 1000 solution of bichlorid of mercury; 5, finish by washing in a 95 per cent. solution of alcohol.

Dr. Doyen, though residing in Rheims, has a private hospital in Paris, where he spends two days each week. His father was professor of anatomy at the Rheims School of Medicine, was engaged in the manufacture of champagne and left a large fortune when he died. The son, instead of lavishing the money that his father left him on yachts and fast horses, seems to have a passion for fitting up palatial operating-rooms and private hospitals. The one at Rheims and the one here in Paris, though eclipsing anything I have seen of the kind, does not seem to satisfy Dr. Doyen's ambition in this direction, so he has bought a piece of ground in a central location in Paris and is erecting an institution which, when finished, will probably be the finest and most perfect of its kind in the world. Though only about 40 years of age, taking all France together, Dr. Doyen has probably the widest reputation as an operator of any man in the republic. In fact, he is looked upon as a kind of surgical prodigy (by those who are not jealous of his rising fame) on account of the daring rapidity with which he operates. In seeking for words to describe his qualities as a surgeon, I will dub him *the lightning operator of the world*. In this light to compare other good operators with him would be to compare the speed of the plow horse on the race course with a Patchen, or the old stage coach of a century ago with the modern express train as a means of locomotion. He has just published a new work entitled "Technique Chirurgicale," which is the finest illustrated publication I have ever seen on

any surgical subject, and will certainly be a valuable addition to the library of anyone who does much surgery, and especially gynecologic surgery. It is a pity that every young doctor who is ambitious to be a surgeon can not read carefully the introduction to this work. Though it is true that the ideas advanced are those of an enthusiast, still there is a world of truth in the opinions which he sets forth. Among the fundamental ideas that he advances is that the surgeon is born and not made. As in painting, sculpture and music the world has produced a Raphael, a Michael Angelo and a Mozart, who were born with a talent that nothing could suppress, so in a like manner must the true surgeon be endowed with a genius that no education can supply. He says: "The English say time is money. I say, '*Le temps c'est la vie*,' or time is life." This idea dominates his soul and actuates his every movement from the moment he seizes his scalpel until his operation is finished. The average man is from thirty to sixty minutes in doing a vaginal hysterectomy; Doyen, in an uncomplicated case, does the same operation in four minutes. I saw him remove, *per vaginam*, a fibroid uterus as large as a large cocoanut by *morcellement* in fourteen minutes, a feat I never saw Péan do within one hour.

While it is an interesting spectacle to observe with what wonderful rapidity a man like Doyen can perform a surgical operation, if we poor, slow, common mortals, not endowed with his talent in that direction should attempt to imitate him, it would be at the expense of the well-being of our patients, though he claims his results are better than those who operate more deliberately. He looks upon aseptic surgery as a most difficult technique to carry out perfectly. The secondary complications, such as pneumonia and the like that follow surgical procedures, he attributes to an infection that occurred at the time of the operation. The great number of assistants that many surgeons have around them he considers as an element of danger, and in all the work I saw him do he had only two, one of them a female nurse who gave the chloroform and a young physician to manage the specula, retractors and the like. Before beginning an operation he selects his instruments, puts them in a receptacle before him and never allows anyone but himself to touch either these or any of his dressings.

Dr. Doyen, in his new work before mentioned, advises in cases where the tubes and ovaries are diseased, to not resort to a vaginal hysterectomy until you have first explored the pelvis through Douglass' pouch and thus ascertain whether such a radical operation as a hysterectomy is really justifiable or not.

Dr. Apostoli, in spite of the great amount of labor he has done in the treatment of diseases of the uterus by electricity and the enthusiasm with which he still pursues his investigations, does not seem to have established among the profession in Paris very much reputation for a form of therapeutics that he seems to have the most unbounded confidence in. It is some years since I first made the acquaintance of Dr. Apostoli, and always when here in Paris I spend a considerable time at his clinic, observing his mode of treatment and watching the progress of the cases that he treats. Like most men who have been pioneers in any field of investigation, the Doctor is considerable of an enthusiast; an enthusiasm with which he does not seem to have inspired many of his professional confrères either in France or America. That the treatment has not been generally popularized is fortunate for womankind, for if not used with great care it is capable of doing an immense amount of mischief. In fact, to make an intrauterine application of electricity safely requires all the antiseptic precautions that we adopt as a preliminary to doing a vaginal hysterectomy. If one follows Dr. Apostoli carefully in the number of cases of uterine fibroids that he treats, though he will observe many failures, yet he will find among them a large number that have been symptomatically cured and will be convinced that we have in this treatment a valuable addition to our often too scanty therapeutic resources.

One of the great obstacles to the introduction of electricity into gynecologic practice is that the men or many of them who ought to employ this remedy in properly selected cases, can operate, and to operate is a much easier thing to do than to treat a patient for months with electricity. But there is another aspect to this question that ought not to be lost sight of, and that is that we find many patients who will not submit to the knife, and to them this remedy holds out some hope of relief. Like everything else of whatever kind that I have tried in the treatment of disease, electro-therapeutics in gynecology has often sadly disappointed me. Yet if I should discard all the remedial agents that have failed to produce the effects that I had hoped and expected of them I should now after forty years of practice find myself occupying the position of a therapeutic nihilist. Guided by my no inconsiderable experience in the use of this agent, I find that there are certain selected cases where it acts well and can generally be relied upon, among which I may mention: 1, the treatment of uterine fibroids of slow growth and especially those occurring in women near the menopause; 2, cases of hemorrhagic metritis that are disposed to relapse after being treated by curettage and other appropriate remedies.

The prominent idea I had in view when I began writing this article was to show that gynecologists here in Paris were possessed with a mania to remove the uterus, and often performed this operation where it was entirely unjustifiable; still the reader is not to infer that I condemn the operation entirely or have not seen it done here frequently where it was probably the best line of treatment to follow. W. S. CALDWELL, M.D.

PUBLIC HEALTH.

The New York City Board of Health and Hydrophobia.—During the past winter the laboratory workers of this board have had in hand experiments with an antirabietic serum and their results have been such that the board has added the Pasteurian treatment of hydrophobia to its list. The poor who chance to fall victims to this rare disease, rare at least in New York, will have the proffer of this treatment free of charge.

To Prevent the Polymerisation of Formaldehyd, Schlossmann adds glycerin and water to the formal, which fills the apartment to be disinfected with a thick vapor. If ammonia is sprayed in the room afterward the odor is entirely removed. This method of disinfection only requires three hours to kill staphylococcus cultures in the remotest corners of the room, and the room can be occupied again the same night.—*Sem. Méd.*, March 10.

Contagious Disease Bureau of New York City.—Dr. Charles S. Benedict, who has been the chief of the Bureau of Contagious Diseases in the New York City Health Department for a number of years, was recently removed by the commissioners and assigned to the minor post of diagnostician. Dr. Alonzo Blauvelt, the chief of the medical school inspectors, was appointed to Dr. Benedict's old place. The position made vacant by the transfer of Dr. Blauvelt was filled by Dr. E. J. Aspell, a former assistant of Dr. Benedict.

Associated Health Authorities of Pennsylvania.—The fifth annual meeting of this body of practical sanitarians will be held in Lancaster, Pa., May 18 and 19, 1898. It is purposed to make educational hygiene a somewhat distinguishing feature. By invitation of the State Board of Health, the Associated Health Authorities and the State Medical Society will, on Friday the 20th, visit the Lancaster County vaccine farms at Marietta, and make an inspection of all its departments. Applications for special railroad rates should be made as early as possible to Dr. William B. Atkinson, secretary, 1400 Pine Street, Philadelphia.

Health in Michigan.—The March report of the State Board of Health shows that the diseases most prevalent in the State during the month, rheumatism, influenza, neuralgia, bronchitis, tonsillitis, pneumonia, pleuritis, inflammation of kidney, diarrhea, consumption, compared with the report for February (*vide JOURNAL*, p. 680), intermittent fever, measles and erysipelas increased in area of prevalence. Consumption was reported at 127 places, measles 100, scarlet fever 69, typhoid fever 62, diphtheria 52, whooping-cough 22 and smallpox at 2 places. Compared with the average for March for twelve years, diphtheria, scarlet fever, whooping-cough, consumption, remittent fever, intermittent fever and pneumonia were less prevalent.

Health in Chicago.—The report of the Department of Health for March gives 2316 deaths during the month, a rate of 1.43 per 1000. The rate for the corresponding month in 1897 was 1.19. Of these 2316 deaths, 606 were of persons under 1 year old and 269 between 1 and 5 years. The principal causes were: Pneumonia, 377; nervous diseases, 276; consumption, 261; bronchitis, 145; acute intestinal diseases, 129; heart diseases, 119; diphtheria and membranous croup, 116; cancer, 64, and typhoid fever, 41 cases. There were 172 cases of suspected diphtheria examined, of which 45 were found to be true diphtheria, 84 false diphtheria and 43 examinations proved unsatisfactory.

Board of Health Can Not Restrict Mode of Laying Floor.—New Jersey gives boards of health power to adopt ordinances; to regulate plumbing and ventilation and secure the sanitary condition of all buildings; to regulate the keeping of all kinds of animals and the accumulation of offal; and to abate any nuisance in any place. But notwithstanding this the supreme court of that State holds, Feb. 21, 1898, in *State vs. Board of Health*, that the board of health of Asbury Park had no power to restrict the owners of a stable to the mode of laying a stable floor prescribed by an ordinance of the board. The owners had the alternative, says the court, of resorting to any other method which would secure the sanitary condition of the stable, though by departing from the prescribed method they took the risk of creating a nuisance. If the stable was a nuisance, the owners must be prosecuted for maintaining a nuisance and not for failing to comply with the plans specified in the ordinance.

Program of Quarantine Convention.—The health and quarantine officers of the Southern States met at Atlanta, Ga., April 12. The following was the official program: Convention called to order by Hon. C. A. Collier of Georgia, chairman of committee on arrangements.

Prayer.

Nomination and election of temporary chairman and secretary.

Chair to appoint—First, a committee on credentials; second, a committee on permanent organization, nominations, and regular order of business.

Committee on credentials shall seat all lawful health officers from the States of Virginia, North Carolina, South Carolina, Georgia, Florida, Alabama, Mississippi, Louisiana and Texas, with full rights and privileges of convention, upon satisfactory evidence of their being such, and shall grant all privileges, except a vote, to members invited by the committee on arrangements.

Report of the above committee.

Election of a president; election of one vice president from each State entitled to representation in said convention; one secretary and one assistant secretary.

Committee report for regular order of business, as follows:

First—president to appoint a committee on plans and resolutions, with one member from each of the afore-mentioned States,

to which all resolutions shall be referred without debate. All plans, codes and forms, after debate, shall be referred to this committee, who shall have the right to report at any time on above subjects. In discussing reports of this committee, no report shall be debated more than two hours. The member submitting a report shall have twenty minutes to open and ten minutes to close the debate, and no other member of the convention shall speak more than five minutes to any one report.

Dr. H. B. Horlbeck, the Health Officer of Charleston, was the permanent Chairman of the Convention. We will publish next week the resolutions which were adopted.

Dr. Horlbeck believes the Atlanta convention has reached the first solution of the problem, and that yellow fever, if it reappears in the South, will be much more easily managed than ever before.

"I do not see," said Dr. Horlbeck to a *Constitution* reporter, "why this convention may not result in a complete solution of the Southern quarantine problem. The convention did its work thoroughly. It was composed of some of the most learned physicians and sanitary experts in the entire country. Those resolutions and regulations were considered section by section by the convention and the resolutions committee, and every word therein should be carefully weighed by every southerner."

"I think there is no doubt about the adoption of the regulations by health officials. The convention was a representative one, and these men will abide by the result. It is safe to say there will be no further shot gun quarantines, and when these regulations are posted in every town and city in the South and the people are thoroughly educated as to the requirements, yellow jack will scarcely be able to show his head in this section again."

"Meanwhile, the press should use every effort to publish all these regulations. The *Constitution's* report of the full proceedings this morning could not have been better. It was excellent, and will doubtless do much good. If every Southern paper would take hold of the matter from now on, and convince the Southern people the regulations must be observed, there will be no trouble. There is no doubt that the Atlanta convention means a world of good for the South."

Formaldehyd Disinfection without Apparatus.—The Chicago Health Department claims to have obtained better results in recent municipal disinfection by the use of formalin without any apparatus than heretofore with the various autoclaves, generators and other devices. Ordinarily these, suspended in the room, were simply sprayed with the 40 per cent. solution through a common watering-pot rose head. A sheet of the usual size and quality will carry from 150 to 180 c.c. of the solution without dripping, and this quantity has been found sufficient for the efficient disinfection of 1000 cubic feet of space. Of course, the sheets may be multiplied to any necessary number.

Cultures, both moist and dry, were exposed for five hours in these experiments—some in sealed envelopes and others wrapped in three thicknesses of sheets, or folded inside of woolen blankets. Of the former, none showed growth after 72 hours' incubation, while the growth was but slight in those wrapped in the blankets. Surface disinfection was thorough, while a much greater degree of penetration was shown in these experiments than that secured by any other method.

The evolution of the gas from the sprinkled sheets is exceedingly rapid, so much so that it behooves the operator to vacate the room within a very few seconds, while, after starting the ordinary generator, he may remain ten minutes or more without serious inconvenience. When the room is opened, after five hours, the density of the gas is still so great as to preclude respiration until after doors and windows have been opened some little time. On the other hand, the air is respirable

within a very few minutes after the sheet has been removed, and there is no lingering smell of formaldehyd for days after, as is the case where the gas is evolved by the action of heat. This is due to the fact that a minimum of the paraform is produced in the evaporation of the solution at the ordinary temperature, and this is retained in the meshes of the fabric instead of being precipitated on surfaces, to be slowly converted into the gaseous form through several days.

If further experiments, which are now being prosecuted by the Department, shall confirm the results thus far obtained, the problem of practical domestic disinfection by formaldehyd would seem to be in a fair way to be solved.

On the Infusorial and other Vegetal Causation of Malodorous States of Stored Drinking Water.—Everyone is familiar with the green slime that collects and accumulates on the walls of the cistern. This is not necessarily due to stagnation, for if water be passed for some time through a capacious glass tube without stopping the flow the same green growth occurs. The growth is essentially of vegetable character and is due to algae and certain infusoria. It is this very growth upon the filter-beds upon which the efficiency of filtration, and especially the removal of micro-organisms depends. Recent researches have shown that this growth is responsible for the objectionable taste and smell which characterize some waters occasionally. The Massachusetts Board of Health has recently made an important experimental contribution to the subject, which shows that the peculiar odors and tastes of surface waters may be due, not always to decay, but to the presence of living or undecomposed micro-organisms, either animal or vegetable, in the water affected. This is not surprising when it is considered how characteristic are the odors of some of the larger plants and animals with which we are familiar. In an interesting series of experiments these investigators have been able not only to add to the evidence upon this point by showing that the natural odor of anabena (a blue-green alga) is due to a peculiar oily product, but also to draw a sharp distinction between the natural odors of the microscopic organisms found in surface waters and the odors produced by their decay. Thus of the diatomaceae, the asterionella, tabellaria and meridion possessed a natural odor ranging from aromatic to fishy, with no odor of decay. All the cyanophyceae, including the anabena, rivularia, clathrocystie, celospherium and aphanizomenom, possessed not only a natural grassy moldy odor, but gave rise also to an odor of decay comparable with that of the "pig pen." Other organisms, as the chlorophyceae and infusoria, possessed natural odors as that of "fish," "ripe cucumbers," "clam shells" and "candied violets." The anabena is marked by a high percentage of nitrogen, sulphur and phosphorus, and these elements would amply account for the production of an offensive smell produced on decomposition. There is, however, a marked distinction between the odors of growth and the odors of decay of the organisms occurring in surface waters. The usual cause of the disagreeable odors and taste occurring in potable waters is found in the presence of large numbers of certain microscopic organisms which secrete compounds of the nature of essential oils. There is no reason to suppose that these compounds are any more harmful than those which give odor and taste to fresh vegetables or to fish. But the "pig-pen" odor is produced by decay, and although the sanitary significance of these partially decomposed compounds in drinking water is yet to be determined analysis would indicate that their effect upon the general health would probably be prejudicial if it were not for the fact that they occur in such minute quantities. These products may even possess the highly toxic characters of certain alkaloids.

NECROLOGY.

GEORGE HOPPIN HUMPHREYS, M.D., Jefferson, 1856, died April 15, at his home in New York City, where he was an attending physician of Trinity Hospital. Born in Philadelphia in 1835, he was educated in part abroad, but returned to this country in 1859 and went to the front as a regimental surgeon with the Ninth New York Volunteers. At the battle of Antie-

tam he was an active brigade surgeon. Five sons are his survivors.

Mrs. JOHN D. S. DAVIS, wife of Dr. John D. S. Davis of Birmingham, Ala., died April 1, 1898. She was secretary of the Woman's Press Club of Alabama and had achieved an enviable reputation in the literary world.

JOSEPH F. COLGAN, M.D., died on April 8 at his home, Brooklyn, N. Y., in which city he was born thirty-three years ago and where he was graduated in 1890 with honors from the Long Island College Hospital. He was the last of six generations of physicians and his father was the late Dr. Joseph P. Colgan.

JOHN D. VAN SAUN, M.D., died suddenly at his home in Jersey City from heart disease April 9. He was born in Jersey City March 21, 1851. He was graduated from Bellevue College in 1873, but gave up his practice two years ago on account of his health. He is survived by his widow and two sons.

FRANCIS R. BROOKS, M.D., Chicago, April 12 aged 31 years. —Bernard Hughes, M.D., New York City, April 11, aged 52 years. —John L. Ingersoll, M.D., Prospect, Wis., April 14, aged 75 years. —Thomas H. Rafferty, M.D. Stafford Springs, Conn., April 10. —Willis W. Hall, M.D., Springfield, Ohio, April 8, aged 42 years. —C. S. Black, M.D., St. Louis, April 6, aged 40 years. —William Irvine, M.D., Evans City, Pa., April 6, aged 70 years.

ASSOCIATION NEWS.

Railroad Rates.—The Western Passenger Association has granted a rate to Denver and return of one half fare, plus two dollars, thirty day limit, for business from Chicago, St. Louis and intermediate points. Tickets on sale June 2, 4 and 5, east of the Missouri River; June 5 and 6, west of the Missouri River. Application for similar rates has now been made to all other Passenger Associations and railroads not controlled by them. Announcement giving rates and rules governing the sale of tickets will be published in the JOURNAL of the ASSOCIATION as soon as decision is made. The rate named is as low as accorded any convention this year. A round trip rate of \$20 from Salt Lake and Ogden, thirty day limit, is also announced.

COMMITTEE OF ARRANGEMENTS.

Section on Obstetrics and Diseases of Women.—Preliminary program of the Section on Obstetrics and Diseases of Women, AMERICAN MEDICAL ASSOCIATION. On the afternoon of the second day, there will be a joint session between the Sections on Obstetrics and the Diseases of Women and Neurology, to discuss the relation between uterine and nervous diseases. On the part of the Obstetrical Section, papers will be presented as follows:

Address by the Chairman, Joseph Price, Philadelphia, Pa. On Pathology, by Lewis McMurtry, Louisville, Ky. Association of Uterine and Nervous Disturbances, by Joseph Eastman, Indianapolis, Ind.

Indications and Contraindications for Surgical Interference, by Franklin H. Martin, Chicago.

These are to be discussed by M. B. Ward, Kansas City, Ferdinand Henrotin, Chicago, and Henry O. Marcy, Boston.

Other papers promised:

Is it Necessary to Drain so Frequently in Pelvic Surgery? by Wm. H. Humiston, Cleveland, Ohio.

Pelvic Inflammatory Diseases: How Shall we Remove Them? by A. H. Cordier, Kansas City, Mo.

Descensus Ovariorum, by A. Goldspohn, Chicago.

Are Ovarian Tumors Rare in Negresses? by I. S. Stone, Washington.

Further Experiences in the Management of Uterine Displacements, by Augustus P. Clarke, Cambridge, Mass.

The Influence of Uterine Curettage and Drainage on Tubal Diseases, by W. W. Grant, Denver, Col.

Etiology and Treatment of Endometritis, by James T. Jelks, Hot Springs, Ark.

Perineorrhaphy and the Structures it Involves, by Byron Robinson, Chicago.

Intraligamentous Growths (Prefers to read by title), by Thomas H. Hawkins, Denver, Col.

Some of the Dangers Incident to Alexander's Operation for Retrodeviation of the Uterus, by Hugh M. Taylor, Richmond, Va.

Why the Operation of Ventral Fixation or Suspension is Unsurgeical, by John B. Deaver, Philadelphia, Pa.

The Curette and Curettage, by Chas. B. Nickols, Denver, Col.

Vaginal Incision in Extra-uterine Pregnancy, by W. H. Wathen, Louisville, Ky.

The Treatment of the Retrodisplaced Uterus, by J. A. Lyons, Chicago.

Puerperal Gonorrhea, by Chas. S. Bacon, Chicago.

Easier Labors and Healthier Offspring, by Ephraim Cutter, New York, N. Y.

Prophylaxis of Gynecologic Diseases, by D. W. Bashan, Neal, Kan.

The Influence of Sex on Disease, by Louis Faugeres Bishop, New York, N. Y.

Compound, Intra-uterine Fracture of the Femur, with Report of a Case, by A. D. Wilkinson, Lincoln, Neb.

A Consideration of Some of the Remote, Unusual and Misleading Symptoms of Pelvic Diseases, by H. D. Niles, Salt Lake City, Utah.

Non-Suppurative Form of Pelvic Inflammation, by L. H. Dunning, Indianapolis, Ind.

Manifestations of Pelvic Inflammations, by H. C. Crowell, Kansas City, Mo.

False Labor Pains, by T. Mitchell Burns, Denver, Col.

The Fallacies of the Forceps Mechanically Demonstrated, by J. J. E. Maher, New York, N. Y.

Hemato-salpinx and Congenital Uterine Atresia, by Alex. Hugh Ferguson, Chicago.

The Treatment of Septic Peritonitis by Irrigation, by T. J. Maxwell, Keokuk, Iowa.

The Special Mark upon the Abdominal Wall of Pregnancy that Exists at the Time of, or Occurs Subsequently to Celiotomy, by Albert H. Tuttle, Cambridge, Mass.

Report of a Case of Bilateral Dermoid Cysts of the Ovaries and Presentation of Specimens, by Jabez N. Jackson, Kansas City, Mo.

The Treatment of Ambulatory Gynecologic Cases, by Denslow Lewis, Chicago.

Anterior Colpotomy and Shortening of the Round Ligaments Through the Vagina for the Relief of all Cases of Retroversion of the Uterus, Simple or Complicated, by J. Riddle Goffe, New York, N. Y.

The Early Diagnosis of Malignant Diseases of the Uterus, by Frederick Holme Wiggin, New York, N. Y.

Anatomic Helps in Abdominal and Pelvic Surgery, by Charles E. Ruth, Keokuk, Iowa.

Pathology and Treatment of Peritonitis, by T. J. Beattie, Kansas City, Mo.

A Case of Tubal Pregnancy with Rupture at the End of the Sixth Week; Operation and Recovery, by J. E. Cowles, Los Angeles, Cal.

Indications for Plastic Surgery of the Cervix Uteri, with a New Method of Operating, by Henry P. Newman, Chicago.

Surgical Treatment of Uterine Myoma, by Henry O. Marcy, Boston.

Maternity Hospitals and Obstetrical Teachings, by George C. Mosher, Kansas City, Mo.

The Relation of Local and Constitutional Diseases to Perverted Ovarian Function, by J. M. Richmond, St. Joseph, Mo.

The Advantages of a Supplementary Sustaining Stitch in the Treatment of Abdominal Hernia, by B. Sherwood Dunn, Boston, Mass.

The Study and Teaching of Obstetrics, by Eliza H. Root, Chicago.

Suspension of the Uterus: The Ideal Method for Retroflexion with Adhesions, by G. Wiley Broome, St. Louis, Mo.

Ovarian Pregnancy, by M. C. McGannon, Nashville, Tenn.

The permanent program must be completed and be in the hands of the Committee of Arrangements at Denver, by Saturday, May 7. C. LESTER HALL, Sec. Section Obstetrics and Diseases of Women.

SOCIETY NEWS.

Texas Medical Association.—The thirtieth annual meeting of the Texas State Medical Association will be held April 26-29, 1898, at Houston, Texas.

American Orthopedic Association meets at Boston, Mass., May 17, 18 and 19, 1898. The preliminary program includes the following papers:

Operative Treatment of Paralytic Deformities, by Bernard Bartow.

A Brace for Cervical Spondylitis, by Wallace Blanchard.

An Inquiry into Epidemics of Infantile Paralysis, and the Late Treatment of that Disease; and Caries of the Spine in Adults, by E. G. Brackett.

Congenital Dislocation of the Hip-Joint, Correction of Stiffness of the Joints by means of the Pendulum Apparatus; and Normal Flexibility of the Anterior Part of the Foot and Means to maintain it, by E. H. Bradford.

Remarks on the Various Gaits of Children, illustrated by some instantaneous photographs, by W. N. Bullard.

Adenoids as a Causal Factor in Deformity, by F. S. Coolidge.

Congenital Absence of the Fibula, by F. J. Cotton and A. L. Chute.

Further Studies upon the Arch of the Foot in Infancy and Childhood; and A Newly-modified Splint for Knock-knee and Bow-leg, by John Dane.

An Operation for the Correction of Web-fingers; and exhibition of; *a*, A Brace for Pott's Disease of the Spine; *b*, A Brace for Lateral Curvature; *c*, A Head Support for Torticollis and Cervical Caries, by G. G. Davis.

Bed Position as an Etiologic Factor in Spinal Curvature, by G. W. Fitz.

The Boot as an Orthopedic Appliance, by H. P. N. Galloway.

A Study of the Final Results in 150 cases of Hip Disease; The Forcible Correction of Spinal Deformities by Stages under an Anesthetic; and the Results of Treatment for the Closure of Sinuses in Tuberculous Disease of Bone, by V. P. Gibney.

An Operation for Un-united Fractures of the Neck of the Femur, by A. J. Gillette.

The Immediate Reduction of the Deformity of Pott's Disease, both with and without Ether; Tendon and Muscle Transplantation (report of forty cases); and the Importance of Twists of the Tibia as the Cause of Toe-in and Toe-out, by J. E. Goldthwait.

Subtrochanteric Osteotomy of the Femur for the Correction of Deformities resulting from Hip Disease (report of ten cases in adults), by J. E. Goldthwait and C. F. Painter.

Bullets and Gunshot Wounds, by J. D. Griffiths.

Spasmodic Torticollis, by H. J. Hall.

The prevention and Correction of Short Leg in Hip Disease, by Robert Jones.

The Manual Treatment of Rotary Lateral Curvature; its Uses and Limitations with a demonstration, by Samuel Ketch.

Local Muscular Weakness as a Cause of Joint Irritation; Faulty Attitude from Muscular Weakness; and A Brace for Pott's Disease, by Robert W. Lovett.

A Demonstration of Some Practical Points in the Anatomy of the Foot, by Robert W. Lovett and F. J. Cotton.

Forcible Correction and Physical Training in Orthopedic Practice, by B. E. McKenzie.

Traumatism of the Spine simulating Pott's Disease, by T. Halstead Myers.

The Anterior Achilles-bursa associated with Exostosis (by invitation) by C. F. Painter.

The Forcible Correction of Deformity in Pott's Disease, by F. E. Peckham.

Congenital Dislocation of the Shoulder; Its Etiology and Pathology, and an Operation for its Relief, by A. M. Phelps.

Forcible Straightening of Spinal Curvatures under Complete Anesthesia, with a report of cases, by John Ridlon.

Operations for Congenital Dislocation of the Hip; Excision of the Hip-Joint; and Hip-Joint Mechanics, by H. M. Sherman.

Deformities in Rickets, by J. S. Stone.

Hallux Valgus Extremus, by A. J. Steele.

A Bivalve Plastic Brace for Pott's Disease; and Growth in Spondylitis, by Henry Ling Taylor.

Report of a Case of Persistent Spasm of the Muscles of the Hip simulating Hip-joint Disease, and Treatment of Contractures by Open Incision and Free Division of all Restraining Tissues (report of cases), by Wm. J. Taylor.

Congenital Dislocation of Shoulder, Forward Dislocation of Hip, and Iliac Abscess of Pott's Disease, complicating Strangulated Femoral Hernia, by R. T. Taylor.

Absence of the Patella (report of two cases); Voluntary Lateral Dislocation of the Knee in Infants; and Experiments with the Celluloid Bandage, by Augustus Thorndike.

Congenital Dislocation of the Shoulder and Birth Palsies, and Report of a Case of Spontaneous Dislocation of the Hip during Typhoid Fever, by L. A. Weigel.

Observations on Anterior Metatarsalgia; and Further Observations on Coxa Vora (a report of twenty-six cases), by Royal Whitman.

Skiagraphy in Lesions of the Hip-Joint, by James K. Young.

Special Equipment of the Children's Orthopedic Ward, University Hospital, by De Forest Willard.

The Establishment of an Orthopedic Appliance Shop, Lemuel F. Woodward.

It is requested that members write Dr. Augustus Thorndike, 601 Beacon Street, Boston, stating what accommodations they desire and which hotel they prefer. If they will state further, either then or later, on what train they will arrive, some members of the Committee will be glad to meet them and escort them to their hotel. The attention of members is particularly called to the request that a synopsis of each paper shall be in the hands of the President by May 7, 1898. In this way alone can members be sure of a place on the final program. The following terms are offered to members of the Association by the hotels named: The Touraine (Boyleston and Tremont Streets), European plan, \$2.00 a day and upward; The Victoria (Dartmouth and Newbury Streets), European plan, \$1.50 to \$3.00 a day; The Brunswick (Boyleston and Clarendon Streets), American plan, \$4.00 a day; The Thorndike (Boyleston and Church Streets), European plan, \$1.00 to \$2.50 a day.

The American Laryngological, Rhinological and Otological Society hold its fourth annual meeting at Pittsburg, Pa., May 11 and 12, 1898. The program includes the following papers:

The Relation Between Diseases of the Nose and Nasopharynx and Middle Ear Inflammation, by Edw. B. Dench, New York.
Hemorrhage of the Lower Throat or Hemorrhage from the Larynx and Laryngeal Tonsil, by Howard S. Straight, Cleveland.

Pathology and Treatment of Tonsillitis Abscendens, by Norval H. Pierce, Chicago.

Rhinoliths, by S. F. Hill, Waterville.

Dysphonia, by T. C. Christy, Pittsburg.

Modern Possibilities in Chronic Catarrhal Deafness, by Sargent F. Snow, Syracuse.

A Case of Rhinopharyngeal Fibroma with Projections Extending to both Anterior Nares, by H. W. Loeb, St. Louis.

Primary Epithelioma of the Antrum of Highmore, by Wendell C. Phillips, New York.

Sarcoma of the Nasopharynx, with Report of a Case, by D. A. Hengst, Pittsburg.

I. Gumma of Pharynx: 2, Rheumatic Pharyngitis, by Geo. T. Ross, Montreal.

Report of Thirty Cases of Antral Empyema, by Frederic C. Cobb, Boston.

Chronic Inflammation of the Pharyngeal Tonsil, by Chas. N. Cox, Brooklyn.

The Tricks of the Trade, or the Mechanical Technique of Operative Rhinology and Laryngology, by H. B. Hubbard, New York.

Remarks on Surgical Treatment of Caries of the Nose and Ear, by H. L. Wagner, San Francisco.

Acute Suppurations of the Middle Ear, by James E. Logan, Kansas City.

Brain Abscess Complicating Chronic Purulent Otitis Media, with Report of Case, by James F. McKernon, New York.

Papilloma of the Larynx; Alcohol in the Treatment, by T. H. Halestead, Syracuse.

Some Remarks on Cholesteatoma of Mastoid, with Report of Cases, by J. E. Sheppard, Brooklyn.

Pseudocousina and Report of Two Cases of the So-called Enochoid Voice, by F. H. Koyle, Hornelleville.

Deductions from a Study of Unilateral Nasal Stenosis, by Lewis A. Coffin, New York.

Hemorrhagic Tracheal Catarrh, Ferdinand Massel, Naples, Italy.

After Treatment of Restored Deflected Nasal Septum, by Chas. W. Richardson, Washington.

Operative Procedures in Staphylophary, by J. C. Lester, Brooklyn.

I, Further Consideration of Basil and Basilar Diseases of the Fauical Tonsils, with Improved Instruments for Treatment of same; 2, Report of Two cases of Nasal Adhesive-tissue Stenosis, Congenital and Scarlatinal, by Robert C. Myles, New York.

Some Observations on the Diagnosis and Treatment of the Singing Voice, by F. E. Miller, New York.

The Proper Mode of Laryngoscopic Examination, with Exhibition of an Improved Mirror, by H. Holbrook Curtis, New York.

Serious Consequences Following Intranasal Operations, by Robert Levy, Denver.

Empyema of the Maxillary Sinus by J. A. Stucky, Lexington.

Perichondritis and Necrosis of the Arytenoid Cartilage, by Wm. Scheppegegrell, New Orleans.

The Relation of Nasal Disease to Pulmonary Tuberculosis, by S. E. Solly, Colorado Springs.

Case of Adeno-carcinoma of the Nose, by Max Thorner, Cincinnati.

Othematoma and Perichondritis of the Auricle, by John O. McReynolds, Dallas.

Mouth Breathing in Children, particularly as the Result of Adenoids, by Arthur G. Hobbs, Atlanta.

Bilateral Abductor Paralysis, with Report of Several Cases in which Intubation was Successfully Used, by W. Cheatham, Louisville.

Oklahoma Territorial Medical Association.—The annual meeting of the Oklahoma Territorial Medical Association will convene in Oklahoma City May 5, 1898, for a two days' session. The following papers are promised:

Bowel Diseases Incident to Hot Weather, by W. K. Harris, McLoud.

Maxillary Abscess and Its surgical Treatment, by A. L. Blesh, Guthrie.

Medical Jurisprudence, by Judge J. R. Keaton, Oklahoma City.

"Where Are We At" in Gynecologic Work, by M. A. Kelso, Enid.

Hernia, by J. H. Rolater, Oklahoma City.

Diseases of the Kidney Encountered as Complications in General Practice, by J. H. Scott, Shawnee.

The Management of Abortions, by G. E. McKeeby, Guthrie.

Best Means of Preserving Our Soft Rubber Surgical Appliances, by G. W. Fairgrieve, Enid.

Obstetrics, by N. W. Mayginness, Stillwater.

Asthenic or Enteric Fever, by A. B. Baird, Oklahoma City.

Rupture of the Perineum and Its Treatment, by J. M. Carson, El Reno.

Typho-malarial Fever, by Wilson Stuve, Oklahoma City.

Emergency Measures in Obstetric Practice, by C. B. Bradford, Oklahoma City.

Suprapubic Cystotomy for Hypertrophied Prostate, by C. A. Cravens, Oklahoma City.

Acute Intestinal Obstruction, by W. J. Muzzy, El Reno.

Curettage of the Uterus, by C. W. Fisk, Downs.

NEW INSTRUMENTS.

THE INTRA-GASTRIC REAGENT CAPSULE—A SIMPLE DEVICE FOR TESTING THE GASTRIC REACTIONS.

BY FENTON B. TURCK, M.D.

CHICAGO.

A ready and convenient method of ascertaining the condition of the gastric secretions in disorders of the stomach has not hitherto been satisfactorily afforded by the appliances at our command. The inconveniences of the stomach-tube have caused resort to other devices, all of which have been more or less unsatisfactory, and have failed to receive general approval and adoption; the sponge tester of Spallanzani and Edinger,¹ Einhorn's² silver bucket, Spaeth's³ pith pellets, etc., are all of them in their way imperfect in their performance, and otherwise objectionable. The tube itself is a disagreeable appliance, and in certain hysterical and nervous patients almost an impracticable one, at least without such compulsory measures as are used with the insane, so that its employment is often given up, to the doctor's discomfiture and the patient's disadvantage. It has, moreover, its actual dangers, and a very formidable list of conditions in which such exist might readily be compiled. Such a one, indeed, is given by Hemmeter,⁴ including pregnancy, certain forms of cardiac and vascular disease, advanced pulmonary disorders, pronounced cachexia, fevers, hemorrhagic tendencies, general or local, and amongst special gastric disorders, ulcerous and malignant growths and various neuroses. Many of these are very real and serious dangers that may be suspected when not positively diagnosed, and thus

⁴ Diseases of the Stomach, 1897.

create an uncomfortable doubt as to the safety and propriety of the use of the tube in some cases. It is also an imperfect appliance in that its presence as a foreign body in the stomach is itself liable in some cases to produce conditions that may vitiate the findings, as I have experimentally demonstrated in several instances to be reported later in the paper.

To meet these objections I have devised the following described apparatus, which I believe permits a qualitative examination of the gastric reactions better than any other yet proposed. It consists in a simple section of a small rubber drainage tube, about one inch in length, through slits in which are passed strips of test papers to the number of three or four, the whole attached to a silk thread and folded up in an ordinary sized gelatin capsule. The thread is passed out through a sealed opening at the end of the capsule and is of sufficient length to enable the tube to be withdrawn when the capsule has dissolved. A small lead shot is appended to insure thorough contact. The reagents I have used in this simple apparatus are congo red, dimethyl-amido-azo-benzol and neutral litmus. Others can be employed as needed or desired, but these have served my purpose in the examinations made. The capsule is easily swallowed, and only a very slight inconvenience is felt at the withdrawal of the tube by the string. If desired, the tube may also be so folded as to act as a bucket on being drawn up, and thus minute samples of the stomach secretion be obtained for bacteriologic or other examination.

The danger of this appliance is minimized and can be neglected from consideration in almost any case. It is not more irritating to the stomach than would be a piece of bolted food, and as compared to the stomach-tube, altogether unobjectionable.

Its advantages are: 1. In patients, who from nervousness, or otherwise, can not take the stomach-tube; who, in attempting it, stop breathing and suffocate, or who find it impossible to swallow it, or are excited by it to violent gagging or retching. There are many of these three classes.

A

B

2. In all cases where the use of the tube is contra-indicated by the reasons given above, either assured or suspected (especially in cases of ulcer of the stomach).

3. It permits as many tests as may be required or desired to be made the same day, or rapidly succeeding one another, without serious irritation or inconvenience. With the tube this would be impossible in most cases, and dangerous or seriously inconvenient in all.

4. The capsule is not as liable as the tube to excite the flow of HCl in the stomach, thus by its presence vitiating the test.

5. Any practitioner can, without special trouble and experience utilize this method at the bedside, in the office, or elsewhere. The patient himself can be instructed how to use it, and can make the tests at such times as are thought best, and save the papers for the physician's inspection.

6. Its results are prompt and reliable, and while not like quantitative tests, they afford at least an approximate estimate by the degree of the color reactions. As a qualitative test it gives exact data as to the presence or absence of free HCl. The congo red reaction is reliable for even a slight trace of free HCl, or of larger quantities of the organic acids, while it does not show the presence of acid salts or combined hydrochloric acid. These are to be detected by the neutral litmus paper. The dimethyl-amido-azo-benzol paper furnishes a still more delicate and absolutely exclusive test for free HCl.

7. It furnishes also, to a certain extent, the means of making microscopic and bacteriologic examinations, and, therefore, in this respect is not seriously inferior to the tube, while superior to it in nearly all others.

8. The capsule being non-repulsive to the patient, is easily taken, and if the use of the tube is afterward indicated he is less likely to object to its employment than if it was attempted without such preliminary experience. This is a practical advantage of more importance than might be at first supposed.

9. As several tests should be made on each case, to secure a positive diagnosis, the capsule has a very marked advantage over the tube in that it does not remove partly digested food, and thus interfere with nutrition.

I have experimentally demonstrated that the presence of the stomach tube by itself is sufficient to produce the reaction of free HCl. In a case of hyperchlorohydrria free HCl was found in the morning in the empty stomach. The viscus was washed out and, after waiting one hour, the tube revealed free HCl.

The next morning the tests were repeated, but after the washing out of the stomach, instead of the tube, the capsule was introduced, and no free HCl was found, no dimethyl-amido-azo-benzol or congo red reactions. Later the tube was introduced and free HCl determined. The tube, therefore, excited the flow of hydrochloric acid, while the capsule did not. This is in agreement with Pick's⁶ statement as to this effect of the use of the tube, while Ewald⁵ says that this may also be caused by the swallowing of the saliva or the pharyngeal secretions, or be due to the presence of substance from the duodenum.

In the above experiments Leube's method was followed in washing out the stomach, fifty cubic centimeters of a 3 per cent. solution of bicarbonate of soda being used. The reaction should then be neutral according to Leube.

The idea of testing the reaction of the gastric fluids *in situ* is not new: it is one that would naturally be suggested to one on considering the disadvantages of the tube. Hitherto, however, no very satisfactory method has been suggested. Spaeth's pith pellets and thread come the nearest to the device I have described, but they do not appear to have received much favor, or to have been adopted for this purpose to any extent. The material is not as convenient or readily available as the test-papers, the unprotected pellet and shot is not as easily swallowed or as unobjectionable to the patient; it is also liable to be affected by the oral or pharyngeal secretions in the deliberate and often difficult process of swallowing, and can not therefore be accepted as a perfectly reliable index of the condition of the

lower viscus. With the capsules all these objections are avoided to the fullest possible extent, and the tests can be multiplied as far as desired.

With the apparatus as above described we have a method that is readily available to the general practitioner, and one that renders possible a much wider extension of a valuable diagnostic method that is too often neglected on account of the difficulties and inconveniences of the ordinarily recommended stomach-tube.

The capsules can be improvised if necessary, but have been made up for me in quantities by Truax, Greene and Co.

MISCELLANY.

Expulsion of Fetus with Membranes Intact.—Myers (*Penn. Med. Jour.*, March), reports a case of expulsion of a mature fetus with the membranes intact. The mother had a week before received a fall, at that time evidently causing the separation of the placenta and the death of the child.

Floating Naval Hospital.—Surgeon-General W. K. Van Reypen, U. S. N., has been inspecting the steamship *Grande Duchesse* with a view to recommending that the vessel be purchased by the government for use as a hospital ship in the war between this country and Spain.

Dying Declarations Need Not be Made All at One Time.—There is no rule of practice or of law, says the supreme court of Louis-

⁵ Präger Med. Wochenschr., 1889, No. 18.

⁶ Lubarsch und Ostertags Ergebnisse der Special. Pathologie, Bd. iii, S. 27. Quoted from Heumeter.

iana, in *State vs. Ashworth*, January, 1898, requiring that a dying declaration should be made all at one time, without interruption, or turning aside to other matters. Neither, as the court holds, does the fact that the declaration was elicited by questions asked the deceased by the witness, instead of being a volunteered statement, render it inadmissible.

New Journals.—A new publication, the *St. Louis Medical Gazette*, is announced to begin with the May number. M. F. Eugman, M.D., St. Louis, is managing editor.—The *Journal of the Alumni Association of the College of Physicians and Surgeons*, Baltimore, Vol. i, No. 1, April, 1898 is noted among our exchanges. It is to be issued quarterly at \$1.00 per year. William S. Gardner, M.D., Baltimore, is the editor.

The Great Virchow.—The *London Times* has recently been guilty of a *lapsus calami* regarding the eminent pathologist of Berlin, by calling him out of his name, as follows: It spoke of him as "the great Virchow, the well known professor of physiology at the University of Berlin." Let us consider that it was a slip of the pen and not a mark of ignorance, but all the same Virchow's friends and colleagues have taken a great deal of innocent merriment out of it.

Professor Rieder of Constantinople.—The Turkish Government having asked for a professor of medicine from Germany, the Emperor has granted the necessary authorization to Dr. Rieder of the University of Bonn. The newly appointed professor is to receive \$6000 a year. He will also have an assistant, who is likewise a German. The latter is to have a salary of \$3000 a year. Dr. Rieder is charged with the reorganization of the medical school. Besides their services at the school these gentlemen will also inspect the military hospitals of the city.

The New York Hospital Library.—Impending changes in the hospital have led to the gift of its old and valuable collection of books to the New York Academy of Medicine. By this accession, the library of the latter will become the largest of the private medical collections in the country. The old and historic building, known as the Thorne Mansion, that occupies a part of the Sixteenth Street front of the hospital grounds, and one which was in turn partly occupied by the library, will be torn down. The improvements that are to be made this spring and summer in the hospital property will aggregate in cost about \$400,000.

Baron Larrey, whom Napoleon I. called "the most virtuous man I have ever known," at the age of 26 years joined the army of the Rhine, and was the physician of the so-called "flying ambulance" for twenty-two years. He was present in sixty great battles, Waterloo was one, and four hundred engagements. He performed numberless operations; it is said that he did two hundred amputations in one day; he operated often on the field, once took off the leg of a high officer in a driving snow-storm, while two other officers held a cloak over his patient. His name stands only below that of Ambroise Paré, his great prototype.

Can Not Be Turned Over to Marine-Hospital Service.—The suggestion was recently referred to the Treasury Department that drugs seized and forfeited to the United States for violation of the revenue laws be turned over the Marine-Hospital Service upon payment of the duty thereon, as the government would thus be likely to derive more benefit than if they were sold at auction, as they usually sell for merely nominal sums. But in reply, Assistant Secretary Howell states, March 18, 1898, that under section 3077, Revised Statutes, all seized goods forfeited to the United States, except when the importation thereof is prohibited by law, are required to be sold at public auction, and that the above suggestion can not, therefore, receive favorable consideration.

Aggravation of Injuries.—The supreme court of Missouri said, when the personal injury case of *Fullerton vs. Fordyce* was

recently before it for the second time, that an injured person should use reasonable care to prevent an aggravation of his injuries, and will not be allowed to recover compensation for such as could have been avoided by the exercise of such care and prudence. Aggravation of injuries by subsequent negligent conduct on the part of the plaintiff may be considered by the jury in mitigation of damages. But to require one who has been injured to take proper and immediate steps to prevent future consequences, the supreme court thinks, is demanding of him a degree of care and an infallibility of judgment which the most skilful physician does not possess. The law requires nothing so unreasonable.

Enucleation of Parovarian Cyst.—Beyea reports (*Am. Jour. Obstet.*, March) a case in which he enucleated a parovarian cyst without removal of its tube or ovary. The cyst was the size of a large turkey egg, the tube stretched over the superior surface, the abdominal ostium patent, and the tube non-diseased. The ovary was of normal size and contained a number of small follicular cysts. A small incision was made through the peritoneal capsule, or mesosalpinx, on the superior surface between the tube and ovary. This was enlarged by tearing and the cyst shelled out. The small cysts in the ovary were punctured and the uterus ventrosuspended, the patient being out of bed in twenty-two days. But one similar case has been reported and that by Kelly in the *Johns Hopkins Hos. Bull.*, Vol. viii, No. 72.

Migraine and Epilepsy.—Rachford (*Am. Jour. of the Med. Sci.*, April), concludes that paraxanthin is an all-important factor in the production of true migraine, also in one form of epilepsy, toxic epilepsy according to his classification of epilepsies into reflex, mechanical and toxic. He has demonstrated that paraxanthin is found in great excess in urine secreted during attacks of migraine, is not excreted in excess in migrainous patients except during the attack, and that a certain class of epileptics also present these conditions in the urine, etc. He has always failed to find paraxanthin in the urine of patients with focal or reflex (hereditary) epilepsy and considers the presence of an excess of paraxanthin in the urine of epileptics an essential diagnostic point in ascertaining the variety of epilepsy from which the patient is suffering.

Cirrhosis of the Liver.—In "A Study of Thirty-seven Fatal Cases of Cirrhosis of the Liver," in the *Boston Medical and Surgical Journal*, March 10, Morse shows that cirrhosis with enlargement, without change in size, and with diminution in size, are equally frequent, and that the size of the liver is increased in a third of the cases. The male sex is more frequently affected. Cirrhosis with enlargement is more common in younger people, and cirrhosis with atrophy in old. The average duration of symptoms is longer in the atrophic cases. The duration of symptoms, however, varies within wide limits in all varieties. Hemorrhage is a not infrequent cause of death in all forms, and a fatal hemorrhage may be the first symptom even in the hypertrophic form. An alcoholic history was obtained in every case in which the subject was investigated. A history of previous malaria, syphilis or gall-stones was occasionally obtained, but in none did it seem of etiologic importance.

Recent Work in Appendicectomy. Bernays (*Medical Record*, April 2) reports a series of eighty-one cases, all acute with one exception, all suppurative or gangrenous, and four complicated with peritonitis, with perfect recovery with one exception. He favors operating in the acute stage and as soon as the diagnosis is made. In one of this series the stump of the appendix was allowed to remain on account of contraindications to its removal. He considers the diagnosis of appendicitis easy and certain in about 99 per cent. of all cases, unless the symptoms be masked by opiates, a practice to be condemned. Twice the appendix was found on the left side of the body. Seventy of

the cases were consecutive suppurative or gangrenous appendicitis. In all but one the appendix was perforated. As to prognosis, he believed that more than one-half will recover from the first attack without operation, that 20 per cent. of all cases terminate fatally, if not operated on, from septicemia, in either the first or second attack, and that two cases in 100 or 150 will terminate fatally in the hands of expert operators.

Hernia in Infancy and Childhood.—Coley, writing on the "Management of Hernia in Infancy and Childhood" (*Archives of Pediatrics*, April), considers hydrocele of the cord as the condition most frequently mistaken for hernia in infants and children, but the history of the case and the general condition of the patient, as a rule, renders diagnosis easy. As to treatment, gentle taxis for one or two minutes should be tried. If this fails, application of hot cloths, from fifteen to twenty minutes, followed by taxis under chloroform, after all preparations for operation have been made. If this also is unsuccessful, immediate operation. As to the use of a truss, the younger the patient, the more probability of a cure from wearing one. That all cases of hernia in infancy are not cured by the truss, he has shown by an investigation during the past year, covering 26,388 cases. Of 15,197 cases over 21 years of age, he found 705 in which the hernia was observed before the age of 14 years. He estimates that 25 to 30 per cent. of children are not cured by trusses.

Prevalence of Herpes Zoster.—In the *Phil. Med. Jour.* for March 26, Cantrell gives in detail the occurrence of this disease in Philadelphia during the twenty years, 1876-1896. The zoster cases numbered 193, or 1.09 per cent. of the patients treated. Of these 183 were whites and ten colored. The youngest person so affected was 3 years old and the oldest 72 years, there being two cases at this latter age. The majority of the cases were persons having indoor occupations. Among the colored the following regions were affected: Pectoralis, four instances; abdominalis, two instances, both on left side; femoralis, three instances and on left side; brachialis, one and on right side. Among the whites the affected regions were: pectoralis in fifty-eight males and four females; abdominalis in eleven males and sixteen females; femoralis in thirteen males and eleven females; brachialis in fifteen males and six females; capillitii in two females; frontalis in five males and two females; ophthalmicus in two males and one female; facialis in two males and two females; nuchal in four males and six females. In 110 cases the left side of the body, in eighty-three the right was affected. About half the cases occurred between 10 and 30 years of age and, in males, laborers were more often affected, cooks and chambermaids among females. There was not a single instance of bilateral herpes.

Miniature Hammers in Suture of Bile Ducts.—Halsted (*Bulletin of the Johns Hopkins Hospital*, April) writes concerning little hammers and their use in suture of the bile ducts. The hammers vary in size to meet all cases. He exposes the duct at the site selected for incision, usually near the duodenal end in the common duct. Before incision he inserts two retractor threads, the incision being made between these. Then, after removing the gall stone, the retractor threads are drawn apart and the hammer introduced, the duct being gently raised and drawn toward the operator by the hammer. Mattress stitches are then applied, one behind the other in front of the handle. The following are the advantages in the use of the hammer: 1. The duct to be sutured can be drawn toward the incision in the anterior abdominal wall and within easy reach of the operator; it can also be manipulated nicely by the hammer. 2. The duct, whether normal or thickened and dilated, is gently expanded by the hammer; hence the stitches can be taken with great accuracy and without fear of including the opposite wall or of occluding the lumen of the duct. 3. The operation is a clean one, because the hammer blocks the duct and this

prevents the escape of its contents and the contents of the gall bladder. 4. With the hammer, wounds of thin normal ducts can be easily and almost infallibly sutured, and hence the surgeon may, if he chooses, fearlessly operate upon the common duct as soon as the obstruction takes place.

County Not Liable for Attendance on Indigent Persons.—The poor laws of Mississippi, the supreme court of that State says, are intended for the class of persons mentioned in the statute who apply for support thereunder, and who are found by the board of supervisors, upon examination, to be entitled to such support, or for persons who, being of the class intended, apply for support, and die before being so adjudicated. But that a person is indigent, and stands in great need of medical aid, does not of itself, the court holds, in Tallahatchie County vs. Harrison, March 14, 1898, entitle him to the benefits conferred by the statute. For example, the court holds, in this case, that the county was not liable for the medical services rendered a man, who recovered from his sickness, where there was no evidence that he had ever been declared a pauper by the board of supervisors, nor that he desired to be so declared, and provided for by the county, though it was in evidence that he was very poor, had a blind wife and several minor children unable to render any assistance for the support of their parents, and a member of the board declared that he thought the man a pauper, and would die unless attended to, and requested the physician to attend him, and promised that he would see that the board paid the claim.

The Non-Equivalence of the Cerebral Hemispheres is discussed in the *Presse Méd.* of January 29, by Klippel, who considers the differences between the two hemispheres sufficient to entitle them to be called the male and the female, as the right seems to be more easily fatigued, while the left is more intellectual and stable. Functional paralysis, hysteric accidents and dynamic disturbances are more frequent on the left side on this account, also the abolition of the reflexes and the more pronounced action of anesthetics, while the localized lesions, of aphasia especially, show the intellectual superiority of the left hemisphere. Anatomic and pathologic—

between the two hemispheres'—and indicates a higher functional state, even account for the phenomena of dual personality.—*Rev. de Psych.*, February.

The X-Rays in Tuberculosis.—Stubbert (*Phil. Med. Jour.*, March 12) reports observations made at the Loomis Sanitarium for Consumptives during the past year, with X-rays in the diagnosis of tuberculous changes in lung tissue, as follows: 1. Slight haziness indicates the beginning of tuberculous infiltration and may or may not be accompanied by dulness. 2. Decided shadows indicate consolidation, the extent of which is in direct relation to the comparative density of the shadow thrown on the fluoroscope. 3. Circumscribed spots of bright reflex, surrounded by narrow dark rings or located in the midst of an area of dense shadow, indicate cavities. 4. Intense darkness, especially at the lower portions of the lungs, indicates old pleuritic thickenings over consolidated tissue. 5. Pleural effusions are shown in dark shadows, the upper level of which may be agitated by succussion. 6. There is no reason to doubt that the effusion of pericarditis would throw a like shadow, which would be distinguishable from the heart shadow above by its greater blackness. 7. Shadows thrown in the first and third stages of pneumonia probably resemble those of tuberculous infiltration. The shadow of the second stage of pneumonia is identical with that of tubercular consolidation. 8. In emphysema and asthma the reflex is abnormally clear, and the movement of the diaphragm is restricted.

Farnacea in the Diet of Later Infancy.—Miller writes on this subject in the *Archives of Pediatrics* (April). He says it is an every day experience to see an infant who has thriven upon the

breast or artificial food during its first year, suffer continually from digestive disturbances when that period has passed, and this is largely due to adding to the dietary, under the impression that the former dietary is no longer nourishing enough, pure milk, bread, potatoes, crackers and strong porridges. This persisted in leads to chronic intestinal indigestion. The child during the second year does not need the large proportion of carbohydrates it receives in earlier life, *i. e.*, 6 of carbohydrates to 1 of proteid, and is not able to assimilate them if given in large amounts in farinaceous food. The child at this period requires more nitrogen in proportion to other food elements than in the first year, and to secure its complete oxidation this should be given with the minimum of carbohydrates. Potatoes should not be given until the twenty-fourth month and then always baked. Orange juice supplies their antiscorbutic properties very well. Potatoes and oatmeal are the most active causes of indigestion at this age. All farinacea should occupy a secondary place in the child's diet until the child has shown his capacity to digest them, which is usually not before the twenty-fourth month.

Infantile Mortality.—Dr. Letters has contributed an article to the *Dublin Journal of Medical Science* upon the mortality of infants in Ireland, in which he says that they are allowed to perish in myriads by feeding-bottles with foul rubber tube-fittings, by farinaceous substances which ferment and decompose as soon as ingested, by neglect, by exposure, by deprivation of the natural nutriment, by preventable causes like premature birth, by preventable diseases like diarrheas and diseases of the respiratory organs. Infants want protection against that killing ignorance which does them to death by artificially induced diarrheas, by convulsions from improper feeding, by marasmus from starvation. Let the question of the saving of infant life receive from the profession that measure of study to which it is justly entitled, let the best means be formulated to stem the infantile death current in our populous urban centers, and let the legislature be urged to deal with these woe-laden conditions with the spirit of humane comprehensiveness. It is not the only country to

The New York University Department.—The teaching faculty of that school has risen as one man, with the exception of one man, against the governing body, the Council. They will resign and, it is believed, will inaugurate a new medical college in affiliation with the Cornell University. The discrepancy that has given occasion to this radical action is an alleged non-fulfillment of certain agreements by the University Council. Until about a year ago the medical school was practically independent of the university. It owned its own property, was governed by its own faculty and conducted its own examinations. Its only connection with the university was that the university granted degrees on its recommendation. About that time an agreement was made by which the property was transferred to the university and the government of the school was vested in the University Council. The faculty was reappointed, and certain stipulations were made as to their prerogatives, the endowment of certain chairs and the financial management of the school. These stipulations have not been satisfactorily met and the faculty stepped down and out, leaving behind them a very valuable property, a large part of which was due to the organizing prowess of the late Dr. A. T. Loomis, whose son is among the come-outers. The staff that is about to retire contains the names of Drs. William M. Polk, Lewis A. Stimson, W. Gilman Thompson, George Woolsey, R. A. Whithaus, H. P. Loomis, F. W. Gwyer, J. C. Edgar and I. S. Haynes. The member of the faculty who remains is Dr. Lefevre, the secretary, who sides with the majority of the University Council. The present site of the school has been occupied since 1870. The buildings were enlarged in 1875, and in 1886 the Loomis laboratory and a

dispensary were added. All these buildings will be lost to the faculty except the Loomis laboratory, which, under the deed of gift, could not be alienated. A late despatch from Ithaca, N. Y., states that a gift of \$500,000 has been made to Cornell by Colonel Oliver H. Payne of New York City, in the interest of the proposed new medical school. Mr. Payne is spoken of as one of the magnates of the Standard Oil Company; he has been interested in medicine for some time, having served as a trustee of New York University medical department.

The Hatfield Research Fund.—At Philadelphia a trust deed has been recorded, the effect of which will be the founding of a memorial prize fund that will be open to American medical men who are doing original work in medicine. This trust deed is executed by Walter Hatfield and Henry Reed Hatfield, who state it is to found a memorial to their father, Nathan Lewis Hatfield, and by it they convey to Drs. J. M. Da Costa, Herbert Norris and Robert G. Le Conte, \$6,000, the income from which is to be paid in prizes, which are to be announced, awarded and published by the College of Physicians of Philadelphia, and each of which is to be known as "The Nathan Lewis Hatfield prize for original research in medicine." The president of the college is to triennially appoint a committee, with the consent of the trustees, and this committee is to select the subject for the best treatment of which the prize will be awarded, under its direction, or the committee may leave the selection of the subject to the authors competing for the prize. This announcement must be made one year before the time fixed for handing in the essays in competition, and the prize can never be less than \$500. The announcement of the first prize will be made next fall, and it must be on a subject of general medicine, medical pathology or therapeutics. The prize memorial essay or research will be published in the transactions of the college under the direction of the trustees. Dr. Hatfield, in whose memory his sons have founded the trust, has been dead ten years. For forty-five years he was in various capacities identified with the College of Physicians, was at the time of his death its oldest member, and was president of the Alumni Association of Jefferson Medical College.

Hardening of Tissues for Microscopic Examination.—Huber (*Jour. of Applied Microscopy*, March) describes three methods of of practical utility to the general practitioner. 1. He places small pieces of the tissue not exceeding one-eighth to one-quarter of an inch in diameter, at once into 95 per cent. alcohol. He uses, in volume, about twenty times as much alcohol as the volume of the tissue to be hardened, advises placing a little absorbent cotton in the hardening fluid and renews the alcohol daily the first three days. Five days hardens the tissue sufficiently for further manipulation, or it may be transferred to 80 per cent. alcohol and stored for future use. 2. If formalin is used it is best as a 4 per cent. solution. It penetrates the tissues readily and hardens pieces not more than one-quarter of an inch thick in twenty-four hours. Fifteen to twenty times the volume of the tissue should be used and kept in a well-stoppered bottle. Transfer to 80 per cent. alcohol for storing away, may be made at the end of twenty-four hours. 3. A third method, one of the best for general work, is the use of Zenker's fluid: Bichromate of potassium, 5 parts; sulphate of sodium, 2 parts; bichlorid of mercury, 10 parts; distilled water, 200 parts; glacial acetic acid, 10 parts; the first three ingredients pulverized in a mortar and dissolved in the water, and just before the solution is to be used add the glacial acetic acid. The tissue, pieces one-quarter to an inch thick, is hardened in twenty-four hours, when they should be washed in running water another twenty-four hours and are then ready for preservation in 80 per cent. alcohol. In this method a precipitate of mercury often left on the tissues may be removed by adding to the alcohol into which the tissues are placed after washing some tincture of iodine, when a colorless

compound, the iodine color disappearing from the alcohol; to remove all the mercury, the iodine should be added from time to time, until no longer removed from the alcohol, indicated by the alcohol remaining brownish in color. If it is desired to make a bacteriologic examination as well as a pathologic diagnosis of any given tissue, alcohol should be selected as the hardening fluid. If it is desired to harden the tissues rapidly and simply to determine the nature of the tissue, formalin will answer very well. If, on the other hand, it is desired to make out the finer details of the protoplasm and nuclei of the cellular elements of the given tissue, Zenker's fluid should be used in preference to the other two hardening reagents mentioned. The tissues should not be washed nor soaked in water before placing in the hardening fluid and should be handled as little as possible.

Washington.

WEEKLY REPORT OF THE HEALTH OFFICER.—The report of Health Officer Woodward for the week ended April 9, shows the total number of deaths to have been 104, of which 60 were white and 44 colored. There were 36 cases of diphtheria and 48 cases of scarlet fever under treatment at the close of the week.

MEDICAL ASSOCIATION.—At the meeting of the Board of Counsellors of the District Association, held on the 13th inst., Dr. Raymond T. Holden was elected chairman, and Dr. Clifton Mayfield secretary.

MEDICAL SOCIETY.—At the meeting of the Society held on the 13th inst., Dr. A. R. Shands read a valuable and exhaustive paper entitled "Prognosis and Treatment of Lateral Spinal Curvature." The next meeting of the Society will be held jointly with the Anthropological Society.

MEDICAL INSPECTORS APPOINTED.—Upon the recommendation of Health Officer Woodward, the District Commissioners have appointed Drs. Louis J. Battle and John L. Norris inspectors, under the Act to prevent the spread of contagious diseases. Their special duty will be to keep under surveillance those persons who were exposed to the case of smallpox which recently developed at the Freedman's Hospital.

Louisville.

McMURTRY.—Dr. L. S. McMurry has removed his office from 231 W. Chestnut St. to his infirmary (formerly the Jennie Casseday Infirmary) 1912 Sixth Street, opposite St. James Court.

CLINICAL SOCIETY.—The regular meeting of this Society was held April 12 at Seelbach's Hotel, the guest of Dr. T. G. Dabney, who read a paper entitled "Ocular Headaches." At the last meeting the resignation of Dr. T. C. Evans, as a member, and as the Society's President was read and accepted, and Dr. Philip F. Barbour was elected to the Presidency.

OPHTHALMOLOGICAL SOCIETY.—This Society being the eighth medical society now in existence in Louisville, was recently organized with thirteen members. Dr. T. C. Evans is President.

HAUSER.—Dr. Catherine Hauser has resigned her position as second assistant physician at the Hopkinsville Insane Asylum and has gone to St. Louis to reside.

SLOANE.—Dr. John Sloane, for many years a respected citizen of New Albany, one of the Fall's cities, died on the 12th inst. He was born in September, 1815, and most of his life has resided in New Albany.

BULLOCK.—Dr. Thos. S. Bullock has gone to Arkansas for a short stay, to obtain a much needed rest.

STATE MEDICAL SOCIETY.—The State Medical Society, under the Presidency of Dr. J. M. Mathews of this city, convenes at Maysville, May 11. It is proposed that Louisville members go all of the way by boat, chartering it and living in it during the session. Owing to the annual convention of another organization at the same place during the State meeting, the one hotel will be taxed to the utmost, and the steamboat will be well patronized. An excellent program is already assured. Those who desire to go by this boat should communicate with the President of the Society, Dr. J. M. Mathews.

Philadelphia.

HEALTH REPORT.—Mayor Charles F. Warwick's recent report for the year just passed contains many medical items of interest. The death rate was 18.72 per 1000, being the lowest for thirteen years; diphtheria prevailed to a greater extent than for several years, as also did scarlet fever; no case of smallpox had been reported (April 4) since October, 1895. There were 2994 cases of typhoid fever for the year 1897, and 401 deaths, one less than the preceding year. The number of cases reported is an increase of 504 over last year, which was believed to be due to the overflow of the intercepting river near Manayunk, November 16. The Mayor takes a strong position against the present dilapidated and insanitary condition of the Municipal Hospital. He says that on the upper floors, where the sick are confined, the food is received in and distributed from bath rooms which are in close proximity to a double row of water closets. The hospital is so overcrowded that in many instances patients with scarlet fever, and those suffering from measles, are put in the same ward. While plans are now being made for the improvement of the building, it has been considered a pest house and such uncertainty keeps the plans held in check. The Mayor says: "This question should be set at rest and acted upon definitely. It is said by those who know that institutions of like character are located in the very center of the large cities of Europe. The science of public sanitation has made such an advance in modern times that surrounding neighborhoods are comparatively safe and free from contagion. So far as this institution itself is concerned, it has never been shown that the health of the immediate neighborhood has in any wise been affected by its presence." For the proper care of patients suffering from smallpox, he recommends the erection of a separate hospital. In 1887 the city used 32,426,779,765 gallons of water against 95,667,466,871 in 1897. The consumption per capita per day was 89 gallons as against 187 gallons in 1897, or an increase in ten years of 100 per cent., which the Mayor thinks is extravagant. Regarding the improvement of the water-supply, he comes out very strongly for a system of filtration.

TWO CASES OF SMALLPOX.—As will be seen in the foregoing, the city of Philadelphia has been free from smallpox since October, 1895. Director Riter, however, gave publicity to a case of smallpox which was discovered last month but the information had been suppressed. The patient, a Mr. Clarity, was employed in a cotton factory and the source of infection supposed to have been through the medium of cotton shipped from the south. The case was reported March 20 and the patient sent to the Municipal Hospital for treatment. The 120 employes in the factory were promptly vaccinated. Notwithstanding all the precautionary measures had been taken by the health officer, Dr. Benjamin Lee, a brother of the first case also became affected with the disease. This case also worked in the cotton mill with his brother and it is not known whether he contracted the disease from the same source or from his brother. It is reported that there is a great deal of the disease in Georgia and other cotton States and that it is gradually working its way north, and the health officer will notify all boards of Pennsylvania in order that wholesale vaccination may be done.

EASTER MUSIC FURNISHED BY INSANE PATIENTS.—For the past two months Mrs. Daniel E. Hughes, wife of the chief resident physician of the Philadelphia Hospital has been endeavoring to control a choir of forty insane patients. The forty singers have chairs on the flower-decked platform, all the women being dressed in white gowns and the men in white linen suits. They are all taught by ear. Many of the choir are said to be epileptics and a usual scene was for one to be attacked while the song was in progress. It is said that music has a quieting effect on the violent cases and has benefited the cases of melancholia at Blockley.

MEETING OF STATE BOARD OF MEDICAL EXAMINERS OF PENNSYLVANIA.—The next meetings of the State Board of Medical Examiners will be held in Pittsburg and Philadelphia at 2 o'clock, June 14. Three Philadelphia physicians are on the board: Dr. S. W. Latta, Dr. H. A. Hulshizer and Dr. Henry Beates.

Cincinnati.

THE mortality report for the week shows: Still births, 5; zymotic diseases, 12; phthisis pulmonalis, 8; other constitutional, 7; local, 44; developmental, 8; violence, 6; total, all causes, 90; annual rate per thousand, 11.55; under one year, 19; between one and five, 7; preceding week 136; corresponding week, 1897, 99: 1896, 142; 1895, 149.

THE annual report of the Cincinnati Hospital has just been compiled and it shows that 4818 patients were admitted of which 3261 were males and 1557 females. There were 378 deaths; 88 were moribund when admitted, leaving the actual mortality 10 per cent. The financial report shows: Expenditures \$115,464.38; indebtedness \$122,613.64; appropriation \$114,000; balance owed from 1896, \$7,149.26. Total excess of appropriation \$8,613.64. The earnings amounted to \$5,289.34, mostly derived from pay patients.

THE annual report from the Branch Hospital for tubercular patients shows: Admissions, 64; males, 47; females, 17; remaining, 21; improved, 8; unimproved, 11; discharged, 14; died, 29; average age, less than 30 years.

Dr. E. G. CARPENTER of Cleveland has been appointed Superintendent of the Columbus State Hospital to succeed Dr. A. B. Richardson, who goes to the Massillon State Hospital.

THE annual report of St. Mary's Hospital shows: Admissions, 2086; male, 1417; female, 669; deaths, 138; discharged, 1742; remaining, 205; nationalities represented, 19; extensive improvements in the way of a microscopic and bacteriologic laboratory have been made during the year, while a new mortuary with a specially designed refrigerator has been built.

Dr. H. W. BETTMANN announces his removal to 20 W. Ninth Street.

QUITE a good deal of deserved criticism has of late been made regarding the methods adopted by one of the larger hospitals to secure patients. It has been found that this institution has been in the habit of sending to neighboring towns its representatives who make it a point to ingratiate themselves into the good graces of the most enthusiastic and earnest church workers and as soon as possible a list of the prospective or possible patients is obtained through this ecclesiastic influence; the skill of the staff, as well as the many advantages of the institution are presented in glowing terms to these unfortunates who are soon persuaded to engage beds for their accommodation.

ACADEMY OF MEDICINE.—At the regular meeting of the Academy of Medicine, April 11, Dr. Joseph Eichberg read a paper entitled "The Treatment of Typhoid Fever without Cold Baths." The essayist stated that the strenuous objections made by typhoid patients to entering a plunge, the frequent occurrence of cyanosis and other alarming symptoms following the emersion, the mental disturbance induced by the thought that after a certain interval they would again be put into the tub, a consideration of the danger incurred in lifting such patients to and from the bath, all led him to adopt a method not open to the same annoyances and one in which the patient could be readily watched by one attendant. He did not regard his plan of treatment as in any way specific; he thought good nursing and especially strict observance of the details of nursing, absolute rest, isolation from friends, etc., as of the greatest value in the treatment. Briefly his plan was as follows: The temperature was looked upon as the principal indication as to the progress of the disease. Every time the temperature reached 102.5 degrees (axilla) or 103 degrees (mouth), the patient was given four grains of acetanilid and a tablespoonful of whisky. If this dose was followed by chills

or other depressing symptoms, it was cut down to three grains or even to two; if it did not control the temperature it was increased six, never more. This kept the temperature down for an average of six hours. An ice-cap was put to the head and kept there until the temperature had remained normal for twenty-four hours. The diet was limited to milk and albumin water. The patients were given fifteen drops of dilute hydrochloric acid three times a day or two grains of quinin in a teaspoonful of chlorin water three times a day. If bowels did not move daily, a simple enema was given. Diarrhea was controlled by Hope's camphor mixture. When the evening temperature had remained normal for a week, the patient was allowed to sit up in bed at first for an hour a day; he was gradually returned to a normal diet, an increase beginning at the time of first sitting up. The essayist had treated over one hundred cases by this method, of which the majority were males; there were in all nine deaths, three of which had received considerable hydro-therapeutic treatment in addition to the acetanilid, so that considering only the cases strictly by his method, but six cases died, making the mortality 4.25 per cent. While acknowledging the alarming and fatal results sometimes following the use of the coal tar derivatives, the speaker plead the smallness of his dose; the fact that it was not continued for a long period of time, the average for all cases being a fraction over six days; the average amount of the drug during this period being 53 grains, a daily dose of eight grains, or two four-grain doses per day; the fact that whisky was given with the acetanilid. The typhoid mortality in the hospital from which these cases were tabulated, for all services and methods of treatment, was something over 10 per cent.

In the discussion, Dr. Dunham reported a fatal case, death occurring two hours after a cold bath, temperature dropping to 94 degrees within a few minutes after removal from the tub; duration of bath, five minutes; cause of death thought to be internal hemorrhage; no autopsy. Dr. Cleveland thought acetanilid acted more as an antiseptic than as an antipyretic. Dr. Fackler believed each patient a law unto himself; thought symptomatic treatment the safest; condemned Brand method of treatment; stated that in the Cincinnati Hospital, during 1897, of the twenty cases treated in that manner, five died, a mortality of 25 per cent.; of the remaining seventy-seven cases, two, which were treated by hydrotherapy, not Brand method, died; of the seventy-five left, all treated by the various coal tars, but three died. He concurred in everything said by the essayist except that he preferred lactophenin and phenacetin to acetanilid. Dr. E. W. Mitchell favors the Brand method in some cases. He thought that now only the worst cases were treated in the Cincinnati Hospital by this method, and quoted Harrie's statistics, collected from an immense amount of material from various countries, treated by method of Brand, with a mortality of 7.5 per cent.; treated otherwise, 10.5 per cent., but said he should not, however, confine himself to one line of treatment. The paper was also discussed by Drs. Oliver, H. M. Brown, G. Mitchell, Adams, Kiely, Ricketts (surgical treatment of perforation), Schenck (condition of blood), Bettmann (antiseptic medication), Friend, Malony, Murphy and the essayist. The Woodbridge treatment was mentioned only to be condemned.

Societies.

The following recent meetings are noted:

Illinois.—Chicago Medical Society, April 20; Chicago Pathological Society, April 11; Kankakee County Medical Society, Kankakee, April 7; McDonough County Medical Association, Macomb, April 5; Western Ophthalmological, Otological and Rhinological Association, Chicago, April 7 and 8. Fulton County Medical Society, Cuba, April 12; McLean County Medical Society, Bloomington, April 7.

Indiana.—Allen County Medical Society, Fort Wayne, April 5; Bartholomew County Medical Society, Columbus, April 5; Marion County Medical Society, Indianapolis, April 5; Tippecanoe County Medical Society, Lafayette, April 4.

Iowa.—Clinton County Medical Association, Clinton, April 5; Polk County Medical Society, Des Moines, April 5; Wapello County Medical Society, Ottumwa, April 5.

Kansas.—Golden Belt Medical Society, Abilene, April 8; Topeka Academy of Medicine, April 11.

Maine.—Maine Academy of Medicine and Science, twenty-fourth annual meeting, Portland, April 11.

Massachusetts.—Boston Medical Society, April 12; Hampden Medical Association, Springfield, April 7.

Minnesota.—Winona County Medical Association, Winona, April 5; Minnesota Academy of Medicine, Minneapolis, April 6.

Missouri.—Hodgen Medical Society, Rich Hill, April 7; Medical Society of City Hospital Alumni, St. Louis, April 7.

New York.—Broome County Medical Society, Binghamton, April 5; Hornellsville Medical and Surgical Association, April

6; Medical Association of Troy, April 5; Syracuse Academy of Medicine, April 5; Utica Medical Library Association, April 4; Dunkirk and Fredonia Medical Society, Dunkirk, April 12; Glens Falls Medical and Surgical Society, April 7; Niagara County Medical Society, Buffalo, April 7.

Ohio.—Lucas County Medical Society, Toledo, April 1; Cuyahoga County Medical Society, Cleveland, April 7; Eastern Ohio Medical Association, Steubenville, April 12.

Pennsylvania.—Lancaster City and County Medical Society, April 6; Lycoming County Medical Society, Williamsport, April 5; Schuylkill County Medical Association, Pottsville, April 5; Cumberland County Medical Society, Mechanicsburg, April 12; Lackawanna County Medical Society, Scranton, April 12; Luzerne County Medical Society, Wilkesbarre, April 6.

South Carolina.—The forty-eighth annual meeting of the State Medical Association, Harris Lithia Springs, April 13 and 14.

Wisconsin.—Fox River Medical Society, Marinette, April 12; Northwestern Wisconsin Medical Association, Stevens Point, April 12.

CHANGE OF ADDRESS.

Anner, J. F., from Shell Rock to Osage, Iowa.
Barker, J. L., from 544 6th Street, to City Hospital, Louisville, Ky.;
Bnfkin, C. W., from Des Moines to Bevington, Iowa.
Carroll, Jr., C. T., from Fountain City to Marvin, Tenn.
Douglass, W. H., from St. Louis to Benton City, Mo.; Duffield, S. P., from Detroit to Dearborn, Mich.
Fankhouer, A. V., from Indianapolis to Marion, Ind.
Gerhards, G. S., from Hot Springs, Ariz., to Ardmore, Pa.; Goins, G. W., from St. Louis to Breckinridge, Mo.
Habenicht, R. H., from Iowa City to Clinton, Iowa; Hughes, O. J. D., from Meriden, Mass., to U. S. Consulate Sonneberg, Germany.
Jones, E. A., from Louisville, Ky., to Sioux Falls, S. Dak.
Klassen, J. P., from 212 W. Taylor Street to 1462 Wabash Avenue, Chicago, Ill.; Kerr, Walter., from 528 Sutler to 1200 Van Ness Avenue, San Francisco, Cal.
Lippincott, J. A., from Castleman Street, to 435 Pennsylvania Avenue, Pittsburgh, Pa.; Longacre, C. E., from East Lynn, Mo., to Westphalia, Kan.; Lumley, R., from 1074 N. California Avenue to 993 Warren Ave., Chicago.
Moody, H. A., from Mobile to Bailey Springs, Ala.; Miller, J. R., from Gaffney to Rock Hill, S. C.; McNamara, F. W., from 107 E. Adams Avenue to St. Mary's Hospital, Detroit, Mich.; McColl, N. J., from Elkton to Twinning, Mich.; Moulton, M. W., from Iowa City to Maquoketa, Iowa; Morgans, S. L., from Iowa City to Dubuque, Iowa.
Nichols, C. L., from 122 S. Lincoln Street, to 227 Winchester Avenue, Chicago, Ill.
Pennington, G. S., from Keokuk to Milton, Iowa.
Prather, J. J., from Los Angeles to Oakland, Cal.
Rectanus, T., from Cincinnati, Ohio to Shelby and Jefferson Streets, Louisville, Ky.
Sylvester, H., from Milwaukee to Mineral Point, Wis.; Schirfee, J. F., from Indianapolis to Fairland, Ind.; Scott, A. C., from 18 Plymouth Place to 825 Willson Avenue, Cleveland, Ohio; Sibley, R. B., from Louisville, Ky., to Clarksburg, W. Va.
Thomas, F. W., from Denver, Colo., to Marion, Ohio; Thrasher, A. B., from 708 Walnut Street to 7th and Race Street, Cincinnati, Ohio.
Van Bensehoten, from Chicago to 1419 Chicago Avenue, Evanston, Ill.
Wyland, G. V., from Chicago to Lyndoo, Ill.; Wall, F. X., from 21 Park Avenue to 103 State Street, Chicago; Williamson, J. L., from St. Louis, Mo., to Lowell, Ark.; Wharton, J. E., from Des Moines, Iowa to Jacksonville, Ill.

LETTERS RECEIVED.

THE PUBLIC SERVICES.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from April 9 to 15, 1898.

Capt. Francis A. Winter, Asst. Surgeon, is relieved from duty at the U. S. Military Academy, West Point, N. Y., and ordered to Jefferson Bks., Mo., for duty at that post.

Lieut. Col. David L. Huntington, Deputy Surgeon-General, retirement from active service by the President on April 10, 1898, by operation of law, is announced.

First Lieut. George Rauchfuss, Asst. Surgeon, the order assigning him to Ft. Apache, Ariz., is revoked.

Major Henry McElderry, Surgeon, is granted leave of absence for four months on surgeon's certificate of disability, to date from his arrival at the Army and Navy general hospital, Hot Springs, Ark.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending April 16, 1898.

P. A. Surgeon L. L. Van Wedekind, detached from the naval academy and ordered at once to the "Minneapolis."

P. A. Surgeon L. L. Spratling, detached from the naval hospital, Philadelphia, Pa., and ordered at once to the "Columbia."

Asst. Surgeon H. H. Haas, detached from the "Vermont" and ordered at once to the "Texas."

Asst. Surgeon E. V. Armstrong, commissioned Asst. Surgeon from April 5.

Asst. Surgeon W. H. Bucher, commissioned Asst. Surgeon from April 5. Medical Inspector D. Dicjerson, ordered to marine headquarters, Washington, D. C.

Surgeon D. H. Bertolette, detached from the marine headquarters, Washington, D. C., and ordered to the "Vermont."

Surgeon W. H. Rush, ordered to the "Dixie" at once.

Surgeon J. M. Edgar, detached from the "Vermont" and ordered to the "Prairie."

P. A. Surgeon J. M. Pickrell, detached from the hospital, Washington, D. C., and ordered to the "Yosemite."

P. A. Surgeon A. M. D. McCormick, detached from the naval academy and ordered to the "Yankee."

P. A. Surgeon M. R. Pigott, ordered to the naval academy at once.

Surgeon L. G. Henneberger, ordered to the bureau of medicine and Surgery.

Medical Inspector M. C. Drennan, detached from the "New York" and ordered home to wait orders.

Medical Inspector C. V. Gravatt, detached from the "San Francisco" and ordered at once to the "New York" as fleet surgeon.

Surgeon A. C. H. Russell, detached from the naval museum of hygiene and ordered to the "San Francisco."

Surgeon F. J. B. Cardeiro, detached from the "Michigan" and ordered to the "New Orleans" at once.

Asst. Surgeon W. H. Bucher, ordered to the "Vermont" temporarily.

Asst. Surgeon E. V. Armstrong, ordered to the "Scorpion."

ORIGINAL ARTICLES.

WHAT CAN WE DO FOR THE CHRONIC INVALID?—A PLEA.

Read before the Kentucky State Medical Society, at Owensboro,
Kentucky.

BY CURRAN POPE, M.D.

Professor of Diseases of the Mind and Nervous System, and Electro-Therapeutics in the Louisville Medical College; Consulting Neurologist to the Louisville Medical College, and to the Louisville City Hospital; Professor of Hygiene in the Kentucky Military Institute; formerly Resident Physician to the Anchorage (Insane) Asylum; Member of the American Electro-Therapeutic Association, American Medical, Mississippi Valley Medical, Central and North Eastern Kentucky Medical Associations, The Kentucky State Medical, and Mitchell District Societies, and Fellow of the Louisville Academy of Medicine.

LOUISVILLE, KY.

A chronic invalid is one who has passed through the acute stages of a disease, and failing of cure, remains in this state, or gradually growing worse, becomes partially or completely incapacitated for labor or the duties of life. In no sense of the word can chronic disease be distorted into meaning incurable disease, for a very large percentage are capable of entire relief, and of the remainder there are few indeed that can not be so improved as to render their lives useful and free from suffering. The failure to realize this difference, and to act promptly, has resulted in the loss of valuable time and entailed much suffering. We must understand that an incurable disease is one which has resisted the scientific, careful and persistent application of all remedial measures, singly or combined, and applied under favorable conditions. Nearly all chronic diseases and disorders fall principally into three classes: 1, the nervous, embracing neurasthenia, hysteria, insomnia, epilepsy, melancholia, migraine, irritable spine, tic douloureux, neuralgia, chronic headache and head pains, drug habits, chronic alcoholism, locomotor ataxia, ataxic paraplegia, diabetes and functional pelvic disorders; 2, the gastro-intestinal class, in which we find the hyperpepsias, hypopepsias, gastric dilatation, dyspepsia, so-called intestinal indigestion and chronic indigestion; 3, the metabolic and nutritional class, including uric acid diathesis, chronic rheumatism, rheumatism, rheumatic and rheumatoid arthritis, gout, the simple anemias, chlorosis, adynamia, phthisis pulmonalis, and obesity. The disease frequently presents in its inception the usual symptoms of one of the above named, but by extension and further involvement, manifold symptoms are superadded, pertaining not alone to the primary disease, but alien to it, and these new conditions increase the symptomatology, modify the past status and make the *status præsens* seemingly bizarre.

In the evolution of man, regular physiologic cycles were established, action was followed by rest, and health maintained. But the nineteenth century, the century of possibilities, has set a pace that few can keep—days of intense struggle, nights of excitement and dissipation, and the law of the survival of the fittest seems our only guiding star. The elusive and delusive dollar, siren-like, lures us on, and health and happiness are considered small sacrifices if success can be attained.

As a result of such nerve wearing exertion, habits detrimental to the economy are rapidly formed, and with difficulty removed. As the strain becomes greater and greater, a hyperexcitability is induced, and recourse is had to stimulants and narcotics to increase the flagging capacities, or to stifle the warnings nature gives. Rest is with difficulty obtained, and hypnotics of all kinds are used, in the vain hope that the pathologic conditions so produced are physiologic, and thus we are afforded an opportunity for watching the slow formation of the drug habitué. Another phase is frequently observed. The patient reveling in the possession of full health violates all the established laws of hygiene, deviates from all the axioms of health, living to learn, later in life, the many penalties of such transgressions. Life, the sum total of active, useful functionation, may be prolonged and its scope wonderfully extended, provided we realize the necessity of high physiologic activity and so arrange our lives as to attain this result. Death, the cessation of all functionation, is in the largest number of cases premature and dependent on witting violation of laws well defined and fixed. Life, and in fact all vital activity, originates in, and is maintained by, the nervous system, and the difference between the living, breathing human being, in whom the exuberance of perfect functionation exists, and the putrefying cadaver, is the difference between the presence and proper distribution of nerve energy and force and its absence, and if its absence will produce death and decomposition, certainly the failure of the great central nerve system to do its work properly will result primarily in the loss of functional activity, which if long continued may produce organic disease, and as to whether organic disease will result is solely dependent on the integrity of the higher brain centers. The differentiation of protoplasm into specialized tissues, and their dependence and interdependence on one another for existence, and the necessity for the harmonious action of the complete whole, brings into view another wonderful and interesting fact, and shows the need of perfect neural action. Any disease, therefore, that starts in any disorder of function, starts primarily in the nervous system, and this disorder will be exhibited either in the neural organs themselves or in some particular set or system of organs, and these in turn by increasing the demand for nerve force, or interfering in its proper storage will extend the baneful influence until what

was primarily simple localized loss of function has become well recognized disorder or disease. As a resultant of such action the perfect elaboration of nutrient material is impossible, metabolism becomes changed, its products toxic, the eliminative function is seriously interfered with, regeneration of all tissues is checked, and a denutritional state established. I have never seen a case of any chronic disease or disorder in which the nervous system did not exert a powerful influence in its causation, its perpetuation or its relief. Natural laws are slow, but certain in their action. No human is exempt from their inexorable and immutable effects—attacking the guilty as well as the innocent, the just as well as the unjust. No disease, governed as disease always is by natural laws, springs suddenly into existence. Minerva-like, full-armed *cap-a-pie*, but by slow and gradual processes the citadel of health is taken, rather than by the brilliant feat of a well-directed charge. The changes of nutrition and its perversion either in functional or organic disease is dependent on the integrity of central nervous action, and if this be true, and I firmly believe it to be so, then all diseases, acute or chronic, functional or organic, toxic or micro-organistic, have as their primary origin, derangement of the central nervous system. Every tissue has its representation, area or cell in the brain, and soundness of the brain and its neural ramifications means integrity of the entire body; means life, health and happiness.

Now, the average American of today is a curious creature. All activity, restless, impatient, irritable, fretful, nervous. The great genius he has exhibited in overcoming the many obstructions found in mechanics makes him believe that his own fertile brain will be able to discover the panacea of health and enable him through the ingestion of delectable powders, esthetic looking pills or questionable liquids, to set aside the result of long years of violation of the laws of health. In all seriousness, we must face the situation and realize its true depth and meaning. Stop and consider that every vision, beautiful or repulsive; every sound, divinely harmonious or gratingly discordant; every impression; every pleasure; every pain; every thought, tangible yet intangible, represents the expenditure of so much energy, the destruction of so much tissue, every unit of which must be restored, every atom of which must be replaced. Destruction is rapid, restoration is slow, and if one chronically invalided can be made to realize to the full extent what I have here stated, and can see that restoration and cure depends on the slow and gradual return of normal functionation, then much has been accomplished by way of preparation. The "chronics" have a hard time. They are given tonic after tonic, and changes rung upon them with all the variations of flats and sharps. The delusive phantom of hope, relying on the slender thread of medicinal means alone, is ever in advance, and sooner or later is replaced by a cynicism as virulent as the hope was intense. But how to meet these cases? The patient feels the irritability, the weakness, and instead of being able to realize the dangers of promiscuous drug taking his obstreperous demands are placed temporarily *hors de combat* by some well-directed tonic, sedative or hypnotic.

Do not understand me as belittling the proper use and sphere of medicinal reagents, but to put our sole dependence in chronic disease, on these means, is to simply court failure and bring retribution on our own

heads and discredit to our profession. Let us recognize our limitations and be honest with ourselves first and then with our patients. Chronic cases are usually the terror as well as the approbrium of the medical practitioner, and the failure to react to the usual measures has led the profession generally to believe that these cases are incurable. Especially dangerous is routine work. "The greatest study of mankind is man," especially man in his normal state. To know him pathologically we must study homo physiologically and realize that every diseased state is simply the unbalancing of the normal and the result of some cause effective. Routine is rank degeneracy and has made and is making of us a nation of drug takers. What these cases need is radically changed conditions, and that condition so changed as to meet the particular case in hand. The ordinary routine of life, with its worries and the constant repetition of perverted nutritional changes, tends to continue the vicious cycle of disease, and if we propose to restore to its natural equilibrium the chronically diseased human system, we must so change and modify his or her condition as to produce profound and lasting impressions by physiologic excitation of functional activity. No practitioner can so flatter himself that inherent in him are powers to relieve disease, but if he wishes to relieve the sick and suffering he must utilize all therapeutic measures in a persistent and scientific manner. The tactful management of the case is a *sine qua non*.

We must always remember that we are treating the particular patient before us and not the disease. "Chronics" present evidence of the many diseases, co-existing, and the dangers of treating the disease and not the patient, are manifold. Do not treat this or that organ, but treat the case as a whole, meeting all the prominent local requirements by proper additional measures, but in all cases making the local treatment subservient to the general and systematic treatment of the case as a whole, and remembering that at the back of it all is the central nervous system, the proper functionation of which is essential to the establishment of health.

Patient and physician must thoroughly understand one another: the truth must be told kindly but firmly, and the truism "that chronic diseases require chronic treatment," should be instilled into the patient in a proper and honest way, and he or she made to realize that no progress will be made except through the slow and gradual process of changed nutrition. The mind must not be turned out like an old horse, to die, but must be directed into the proper channels of thought, otherwise it may take too great cognizance of its corporeal coadjutor. We should inculcate into the chronic invalid the necessity for the state of calm possessed by the high caste Hindoo, whose soul has passed into the calm waters of knowledge, high above the wear and tear of surging and conflicting passions. Hobbies are necessary. The study of astronomy, with its millions of twinkling lights, mechanics, biology, archeology, architecture, art and literature, offer rich fields from which the tense and discordant vibrations of inharmonious nerves may turn and obtain in interested study or reflection, striking symphonies of peace and rest. Few Americans know the meaning of neural rest and mental calm. The theory is correct and beautiful, but to put it into practical operation requires judgment, knowledge of human nature, and a peculiar personality adapted to the work.

Proper and wholesome inspiration, judicious, sympathetic vibration, and contagious personality enter much into the effectiveness of our efforts. To inculcate calm or cheerfulness, the inculcator must be a living example of his own ideas. Every improvement should be made a text for directing his warped mentality into broad and proper channels. Good literature, judiciously suggested, is a valuable aid, and the comic journals, the short story, where the interest is well maintained, may be made to contribute to the quota. The theater, in both health and disease, is a favorite prescription of mine, for the overworked, the nervous, and the invalid in general. Light opera, comedy and the many interesting society and romantic plays upon the stage today, are to be preferred. Forbid tragedy and melodrama. I am thoroughly satisfied of one thing, and that is that proper and cheerful thoughts flush the brain with bright arterial blood, increase functionation and hasten nutrition, and at the risk of being prolix I will venture to again call your attention to the fact that as we better the brain function we better our patients mentally and physically. The converse is true that evil thoughts, depressing emotions, all produce profound retrograde processes. To teach a patient the philosophy of life, its aims and possibilities, is a mission whose work is never done, and whose power for good is limited only by our opportunities. For the benefit of the corporeal and physiologic side of our patients, we should lay down the laws of hygiene, regulate the patient's life and habits, and insist on the performance of these as a duty. Even when the sufferer returns to the ordinary avocations of life, to daily labor, to hourly care, these suggestions, these laws must be the rudder and the compass by which he steers his fragile bark of life through the turbulent waves of existence, into the smooth and placid waters of health and happiness. To arrive at a logical conclusion, a proper promise is essential; to arrive at a proper therapy, a proper preliminary investigation is necessary. A thorough and carefully written record for present and future reference should be made, grouping symptoms under well defined headings, followed by an inquiry, oral and physical, into the status, past and present, of the various organs *seriatim*.

There is probably no field more neglected by the clinician than the proper and exhaustive examination of the secretions, not alone for diagnosis, but for the elimination or confirmation of suspected organic disease. They point out indisputably the true line of therapeutics. The urine should be most carefully examined and re-examined, chemically, microscopically and by the method of Haig, for the relation of uric acid to urea.

The hemic function has been sadly neglected. The quantitative estimation of the hemoglobin, counting the corpuscles white and red, and properly differentiating them, by means of the Ehrlich stain, will reward the investigator for his time and trouble. Even the examination of the blood by the microscope alone will frequently put new dresses on old facts.

The stomach needs careful consideration. Accurate knowledge concerning the viscus is required, and to this end a proper test-meal should be given, the contents removed at the proper time for thorough and scientific consideration. This method of removal is practically devoid of danger, and the discomfort of its use can be reduced to a minimum. In the examination of the juice removed, macroscopic and micro-

scopic inquiry should be first performed. The average examination of the gastric contents I do not consider to be of much value, but a quantitative analysis after the accurate methods of Hayem and Winter, furnish a basis for rational and scientific therapy.

Much information can be obtained from an examination of the muscular state by means of the dynamometer. The whole may be summed up in the statement that we can not know too much about our patients and their condition, and when once we have mastered every detail of our case we are in the best possible position to scientifically administer any remedial measure. The therapeutic field is vast. No one remedy possesses any particular potency to relieve the case, except in rare instances, and it must be by a judicious and rational combination of all measures that success is obtained. A careful dietary must be arranged based upon the result of our analytic work, the idiosyncrasies and peculiar symptoms of our patients and the actual physical condition present in the viscus.

Now, having placed our patient under the most favorable of circumstances, we are ready to apply a number of remedies, medicinal and mechanical. Limited time prevents more than the most general considerations of the subjects mentioned. In the cases herewith appended, detailed consideration of their action will be entered into in explanation of the results obtained. The vast power for good, resident in the great mechanical treatments, when carefully applied, result largely through their capacity to influence nutrition, stimulate the vasomotor tone, increase nerve action and favor elimination. In the hands of the tyro they are as potent for evil as for good, being no exception to the universal rule bearing on such conditions. Other discouraging features attend failures by the unskilful, for lack of confidence is brought about, not only in the physician himself, but in the methods used. There is one cardinal feature that I can not too strongly insist on, and that is the necessity for the persistent, patient and painstaking following-out of the treatment. Ephemeral results after a few weeks of treatment may be observed, but real decided improvement, permanent in effect, can only be obtained by the slow and gradual changes, brought about by better nutrition and improved nerve force. Time itself, rest, vacations, change of air and scene, are, in my opinion, useless in the therapy of chronic disease, but as a "top-off" to the proper therapy, they become valuable aids. I have observed some rather curious facts in regard to the progress of these cases. Nearly all feel worse and appear worse, during the early stages of treatment—a fact very depressing to the patient, and initiating a period when it requires all his will-power and confidence to bridge him over. I believe this to be due to a species of intoxication, caused by the presence of toxic and metabolic products of retrograde tissue metamorphosis circulating in the blood, irritating and depressing the cerebrospinal system, interfering with active functionation, preventing proper oxidation, and taxing the eliminative organs to their utmost. Free relief through the cloaca maxima, by means of a mercurial, may hasten matters considerably and afford temporary relief.

Another curious fact: So often have patients complained of certain symptoms appearing during recovery that were present in the first stages, that I have been forced to ask myself if chronic disease returns

to the normal over the same road it traveled during its downward course?

We can not antidote disease; we can not crush it out, but can relieve it through a proper stimulation along physical lines of the *vis medicatrix nature*, and why should not the natural forces reascend the hill of health in the reverse order in which they have been so long descending? The laws of nature are truly fearful, and wonderfully active, and the greatest laurels await him who masters the incalculable intricacies of cellular nutrition and activity.

4. Turning to the practical means, by which the longed for desideratum may be obtained, many medicinal reagents are presented for our consideration of which but few are of the slightest permanent advantage. Medicines, as a rule, are of little value in chronic ailments, and should be prescribed usually for some definite temporary need or to supplement some other method of cure. The medicinal field is too limited to receive much consideration. The laxatives are by far the most useful of all the drugs for temporary effect. Next, I would rank nux, strychnia, bromids, iron, quinin, iodids and mercury. They help some, but only a little. The delusive "tonic" when given alone has cast more discredit on medicine than all the other classes of drugs combined. We must realize our limitations and regulate our practice accordingly.

Massage and mechanical vibration.—Manual massage has proved of great value in selected cases, and especially when used in the Weir Mitchell treatment amplified by hydiatic measures of a stimulating variety. Its application requires a technique, very considerable knowledge of anatomy and physiology, a certain amount of pathology, an infinite amount of tact and good sense. Ordinary rubbers are worse than useless. I have been very much astonished at the frequent use of general massage (?) so-called immediately after hydrotherapeutic measures, and believe that some of the discredit that has been reflected upon this great measure, has been due to this irregular and pernicious practice by ignorant and unskilful bath attendants. Its action is far reaching. Muscular fatigue is relieved, the motor and muscular function by pressure and stretching is stimulated and, by its local action, congestion and inflammatory deposits are removed. By the combination of massage, (rubbing) and petrisage (kneading) the veins and lymph channels are emptied, and the action of the heart not only accelerated but bettered. Abdominal massage reduces the heart beat, increases the appetite, removes flatulency and residue in the intestine, and overcomes constipation. The general effects obtained are through the stimulation to the circulation, the increased elimination of toxic products, better appetite and digestion, greater assimilation, heightening of the blood-forming functions, and increased nutritional changes.

Mechanical vibration in its general effect resembles massage, but I am constrained to believe that, after seven years constant use of both, its effects are more far-reaching and permanent than those of manual massage, though each possesses some advantage in particular cases. This I believe to be due to a natural tendency of all matter to vibrate, and vibration so applied acts more along natural and normal lines than massage. Mechanical vibration, commonly called mechanical massage, is applied through the intervention of specially designed machinery and instruments run by means of power at a certain rate of speed. The influence it exerts is most profound, and the results

are similar to those of manual massage, but more permanent.

Hydrotherapy.—I must preface my remarks on this agent by an apology for their superficiality. My constantly growing experience in its use, has shown me, that this agent is one by means of which results can be obtained so astonishing to the ordinary observer as to shake his belief in the question of incurability of disease. No case must be pronounced incurable until proper and scientific hydiatic measures have been tried. In its wide range of temperature variation, with the ability to regulate the force of its impingement upon the surface, in its potent power to influence the peripheral blood vessels and nerve terminations, in its wonderful and transferred effects upon brain, cord and viscera, in its eliminative, hemogenetic power, in its capacity to increase assimilation and change perverted nutrition it stands abreast with, and equal to, any mode of therapeutics known to mankind. Perverted function, sluggish circulation, poor elimination, deficient excretion are corrected and improved through its careful and systematic application. This treatment, like all others, should be prescribed by the physician alone, due care and regard being paid to the mode of treatment, the temperature and its proper changes, pressure, duration, preparatory arrangements and the final accessories. That nervous excitement and perturbation is allayed, that tissue metamorphosis is hastened, that increased absorption of oxygen and elimination of carbon dioxid takes place, that exhilaration and increased muscular power are present, is a daily observation. When due care is exercised in its application, we may expect far-reaching and permanent results.

Electrotherapy.—This agent has reached a well recognized place in medical therapeutics at the present time which the preceding mechanical treatments have not succeeded in doing. But a few years only will elapse before recognition will be given to them. Many of the most intelligent practitioners of the present day use the electric current, realize its value, and know the practical results obtained by its application. The constantly increasing activity along this line of work has of late years added much to our armamentarium of valuable and interesting means for the relief of disease. These four great mechanical methods, together with a rational and careful application of hygienic laws, supplemented by the temporary use of medicinal remedies, constitute the means of him who seeks a class of patients usually hopeless and pessimistic in their regard for the profession and its capabilities. If success would crown our efforts, it must be in the intelligent use, not of any single line of therapy, but all. Patients do not, as a rule, appreciate the value of these remedial measures, are prone to demand too much and expect wonderful returns in a short time.

Foreign Bodies in the Ears.—Schuh extracts a foreign body by fastening a small piece of sealing wax in the end of the galvanocantery loop twisted spirally to hold it. It is then inserted in the ear and, as it comes in contact with the foreign body, the current is turned on for a moment, which softens the wax and it adheres to the foreign body, the current turned on another moment if necessary. It is then left undisturbed to cool and harden, when the foreign body is drawn out with it. To extract a glass bead the wire is dipped a moment in melted sealing wax and then inserted in the hole in the bead. He considers a mixture of equal parts colophony, white wax and sealing wax better than the latter alone. — *La Revue Méd.*, March 23.

THE X-RAY FROM A MEDICO-LEGAL STANDPOINT.

Read before the Fourth Annual Meeting of the American Academy of Railway Surgeons, held at Chicago, Oct. 6-8, 1897.

BY R. HARVEY REED, M.D.

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY AND CLINICAL SURGERY, OHIO MEDICAL UNIVERSITY; SURGEON TO THE PROTESTANT AND UNIVERSITY HOSPITALS; CHIEF SURGEON

C. S. AND H. R. R.
COLUMBUS, OHIO.¹

The proper relation which the X-ray should hold in medico-legal medicine has not yet been determined.

When the announcement was made of the discovery of the Röntgen ray, it was given a wider scope of usefulness than clinical experience has yet been able to demonstrate. It is not my object to find fault with the skiagraph or cast any reflections upon the benefits which humanity has or may derive from its use, yet I feel from the experience of myself and others that it has not reached a degree of certainty that warrants us to depend upon it as a safe and positive method of diagnosis.

In ordinary photography, in which a photograph is taken of the real object itself, the position, the light, the focus and many other auxiliaries may greatly modify the photograph taken of the same person on the same day with the same apparatus, in the same gallery. But when we consider that an X-ray is not a photograph of an object, but is believed to be only a photograph of its shadow, we can readily understand the additional complications which prevent the possibility of getting a true and accurate picture of the object as it really exists.

That the X-ray has been beneficial and will become more so in the future is not disputed. The object of this paper is to consider and so far as possible determine its true medico-legal value. I am quite sure that neither the medical nor the legal profession desire to admit as final evidence anything which is surrounded with a halo of uncertainty. For this reason the courts have very justly decided that the witness must tell what he knows in regard to any particular case and not what somebody has told him. If it is deemed proper to apply this rule to the witness there should be equal caution about admitting testimony in the form of an X-ray which is believed to be nothing more than the photograph of the shadow of an object and not even the photograph of the object itself.

As has been well said by Professor DaCosta: "The X-rays are not electricity, though generated by electricity. They are not light, though possessed of some of the powers of light. They are not cathodal rays, although they take origin from the wall of the tube where the cathode rays fall. No man knows what these rays are, but we are getting a clear comprehension as to what they can do." He also says, "great discoveries suddenly made are rare in medical history. The chain is forged but very slowly, and many a one has swung the sledge of thought to complete a single link. Several times in the history of our science, a startling discovery has sprung from the brain of genius, a discovery unheralded, unlooked for, and complete as Minerva when she came from the brain of Jove. We at once recall as belonging to this

species, the discovery of the circulation by Harvey, the application of the ligature by Paré, the discovery of anesthesia by Morton, the introduction of vaccination by Jenner and the construction of the germ theory by Pasteur. To this short list must be added the discovery made in the Bavarian University of Würzburg by Professor Röntgen in October, 1895, and made public Dec. 5, 1895, in a paper notable not only for its profound learning, scientific accuracy and logical force but also for its genuine and beautiful modesty." . . . "This discovery is something startling and unique. It is a pathway blazed through a jungle which hitherto no one even thought of entering. It annihilates notions which have come down to us through all the centuries of time. It overturns with revolutionary thoroughness what were but yesterday the plainest axioms of physics. Much has been learned of this newly-recognized force, and much is left to be learned. The pathway has been blazed, but there are yet dragons to conquer, there are yet giants to slay."

One of these giants that is yet to be slain, is how to determine accurately the exact location of a foreign body in the human economy. From a surgical as well as a medico-legal standpoint it is of the highest importance that we not only know there is a foreign body, but we must know its exact position in the majority of cases, in order that an operation, if such is necessary for its removal may be successful, or to determine if the foreign body will continue to be a permanent injury to the patient. Before the Röntgen ray should be admitted to the courts as a reliable source of evidence these conditions should be overcome by better apparatus, and more careful study of its use, as well as the position of the patient, in our attempts to locate not only a foreign body but a fracture or a callus, the result of a fracture.

It is comparatively easy to locate a fracture or a foreign body in the hands or feet and the responsibility in such cases, both from a surgical and medico-legal standpoint, is as light as it is easy. On the contrary, when it is necessary to locate the exact position of a bullet in the brain, or a foreign body in the abdominal or thoracic cavity, the difficulty is increased, and the responsibility of the rathigrapher as well as the surgeon, not considering the danger to the patients, is very greatly enhanced. I recall a case in which a man had accidentally shot himself in the forehead. A few months later he was seized with epileptic convulsions. He was taken to an expert radiographist, whose apparatus is of the best quality, and yet he failed to locate the bullet which, on operation by the writer, was found to be imbedded in the skull, having displaced a portion of the cranium equal to the size of the bullet and forced it through the dura mater, while the bullet itself occupied the perforation made in the skull, and yet, all attempts to locate this bullet, which lay between the periosteum and the dura mater, was absolutely futile, but the facts showed that the bullet was there and the clinical condition demonstrated sufficient irritation to produce epileptic convulsions. Here is a case, which if circumstances had brought it into court, and the X-ray had been admitted as testimony, the evidence would have been far from being "the truth, the whole truth and nothing but the truth."

At the recent meeting of the AMERICAN MEDICAL ASSOCIATION, held in Philadelphia, it was my pleasure to listen to a paper, presented to the Section on Sur-

¹ Since preparing and reading this paper the author has removed from Columbus, Ohio, to Rock Springs, Wyo., and assumed the duties of Superintendent and Surgeon-in-Charge of the Wyoming General Hospital, Assistant Surgeon of the U. P. R. R. Co., and Surgeon-General of Wyoming, etc., etc.

gery and Anatomy, on the "Röntgen Ray Skiagraphy," by DeForest Willard, M.D., of Philadelphia, which was illustrated by numerous skiagraphs of normal and abnormal structures. In this paper he said: "Although skiagraphy is a most valuable assistant to the surgeon, yet a word of caution is necessary. It has been most conclusively shown that the position of the tube, the direction of the rays, the method and time of the exposure, the magnification of portions of an object not in contact with the plate, the elongations of shadows from distant portions of an object together with other varied conditions, may so completely distort the resultant image, that error is certainly possible. A fracture may appear to exist when a bone has not been broken: and, on the other hand, it has been shown that a known fracture produced by osteotomy is not discoverable. These facts make it imperative that the medico-legal value of these radiographs should be considered carefully, and pictorial evidence should receive only its due amount of consideration in connection with clinical evidence. Clinical evidence should have and does have, large weight in the question as to results after fracture and other injury. Knowledge obtained by long experience and positive indications is far more valuable than any representation visible alone to the eye."

In this connection, in our efforts to make an accessible pathway of the blazed trail which has already been referred to by Dr. DaCosta, I call your attention to the accompanying skiagraph, (Fig. 1) which was recently taken by Professor Early of Columbus, Ohio.

Case 1.—A child, 2½ years of age, July 18, 1897, swallowed a shawl pin some two and one fourth inches in length, the diameter of the head of which was one fourth of an inch and the longitudinal diameter three sixteenths of an inch. It was under the care of competent physicians until September 3, when it was brought to Columbus, where the skiagraph referred to was taken. This showed that the head of the pin lay just above the sixth rib. The point of the pin extended upward to a point between the second and third ribs, and apparently in front of the vertebra. An analysis of this case would show that it was impossible for this foreign body to have passed down the trachea and be located in either of the large bronchi and at the same be at this particular point. In addition to this there was no respiratory interference that would of necessity exist were this pin imbedded in the lung.

General emaciation and interference with the digestive tract, together with this skiagraph, led us to believe that the pin had been swallowed and in some way had become lodged in the esophagus, and as a result we determined to make a gastro-tomy in the hopes that we could remove it.

Sept. 4, 1897, the stomach was opened at a point near its juncture with the esophagus. I passed my finger through the lumen of the esophagus up to the fourth rib and found it entirely free from any foreign body, but discovered a fluctuating mass a little to the left of it and the vertebral column, which on pressure, ruptured into the esophagus. A large quantity of pus escaped into the stomach and was discharged through the mouth, and for a time threatened the life of the child from strangulation. After having thoroughly washed out the stomach and esophagus and having cleansed the throat and mouth, a steel sound was passed from the opening in the stomach to the pharynx without the least difficulty, but I failed to detect the presence of any metallic substance. This was removed and a No. 18 soft catheter was passed from the mouth to the stomach with the same results.

In this exploration it was quite easy to pass the finger underneath the heart, along the abdominal aorta and feel their pulsation distinctly, and also feel the vertebra, but we were unable to find the pin and abandoned further search for the time being. There were several reasons for doing so; 1, we were disappointed in not finding the pin in the esophagus, where we were led to believe, from one version of the history of the case and the X rays, it was located; 2, because from another version of the case there was a question as to whether the child had swallowed a pin, as the evidence in that connection was circumstantial; 3, that possibly the evacuation of the abscess would give relief, especially if the latter theory of the history of the case were

true. No one saw the child swallow the pin, but its mother knew it had taken a pin from her clothing, had gone to its grandfather and in a few minutes later began coughing. The pin could not be found and the conclusion was naturally arrived at that it had swallowed it.

The gastric and abdominal wounds were closed with pyoktanin catgut sutures, both of which healed by first intention, and on the fifth day the child was taking nourishment by the stomach without difficulty. The irritation, however, continued, resulting in a rise of temperature and paroxysms of coughing, which after the operation were frequently followed by a discharge of pus, indicating the continued presence of an abscess, which would evidently fill up, making pressure upon the nerves thus inducing these paroxysms, which were temporarily relieved by the discharge of the pus.

The child was again taken to Professor Early, placed under an anesthetic and examined carefully with the fluoroscope in addition to taking skiagraphs antero-posteriorly and laterally. At this time the X-ray examination showed that the head of the pin was just below and a little to the left of the superior margin of the manubrium and the point of the pin high up in the trachea.

The child was losing strength rapidly, and unless relief could be obtained by operative interference, it would succumb in a short time, as it came near strangling several times from the discharge of pus. Sept. 4, 1897, it was decided to make a laryngotomy and if possible remove the pin which, judging by the radiograph, was now believed to be in the trachea. The child was placed under an anesthetic and an incision made through the skin, when the child coughed and a gush of pus from the mouth followed and it was drowned on the operating table by the pus, which in spite of all our efforts was inhaled into the lungs to such an extent as to produce asphyxia. The operation was now converted into a postmortem which revealed the point of the pin protruding obliquely into the trachea about one-fourth of an inch, just at the bifurcation of the bronchi, while the body of the pin passed underneath the esophagus and the head of the pin was located between the fourth and fifth ribs close to the spinal vertebra, immediately underneath the heart. The pin was very much corroded and required considerable force to remove it from its moorings, thus convincing me that it had not changed its position, but the apparent change was due to an optical illusion which I am unable to explain.

The abscess cavity which was large enough to contain nearly two ounces of pus, opened into the esophagus at a point near the juncture of the vertebra and the fifth rib, and was located just to the left of the vertebra and extended to the inferior margin of the pericardium, which also formed its anterior wall, and upward for a distance of about one and one half inch, following the connective tissue along the left side of the esophagus. How this pin ever got into this locality remains an open question. The fact that the pin was very much corroded and its removal required no small amount of force with the use of forceps indicates that after the pin had become imbedded it had not changed its position up or down, as indicated by the radiograph, but had remained fixed in its position causing the irritation and infection, followed with suppuration, hectic fever, emaciation and finally death by strangulation fifty-eight days after it had been swallowed.

The lesson to be learned from this case is that the X-rays were not a safe guide to the discovery of this foreign body, and notwithstanding every effort was made by Professor Early, and no time or trouble spared, on his part, to locate the pin accurately, the operation and postmortem demonstrated that while the X-rays showed the presence of the pin, they did not locate it so as to be of any material assistance to the operator.

Case 2.—A target man, in the employ of a railroad in Ohio, was sent to the Protestant Hospital, Columbus, Ohio, Nov. 4, 1896, by the company surgeon for a comminuted fracture which occurred November 2. There was a history of a previous fracture of the tibia of the same leg at about the juncture of the middle and lower third, which had occurred some years before, resulting in about one and one half inches of shortening. When he arrived at the hospital the temporary dressing was removed and several large blebs were observed at different parts of the limb between the ankle and the middle third, evidently due to impaired nutrition. On further examination it was discovered that there was a comminuted fracture of both bones of the left leg, which were fractured at different points between the ankle and the knee as is shown by the accompanying skiagraph, which was taken by Professor Early. (Fig. 2.)

Owing to the devitalized condition of the soft parts, it made it impossible to use extension as there was extensive sloughing, which necessitated dressing every day, and prohibited the use of dressings which otherwise would have kept the bones nearer their normal position.

An examination of this skiagraph will impress you at once that there had been considerable disturbance of the bony structures of the leg, and yet it shows that the general alignment of the limb was good, which was the fact, but owing to the causes above referred to, the bones could not be held in place, nevertheless recovery took place with but three and one-half inches of shortening, or in other words, two inches shorter than it was prior to his last accident. The general appearance of the limb was fairly good. The man is working every day, wears a brace and a shoe with a thick sole, and gets along remarkably well.

If this radiograph should be taken into court and submitted to a jury, without taking into consideration the facts in the case, it would certainly be very misleading and would indicate a much worse condition of the limb than the clinical facts in the case would warrant. This shows seven distinct fractures of the bone and yet, with all that, we have only two inches more shortening than existed in a previous fracture of the same limb.

Case 3.—In this patient (Fig. 3), there was a fracture of the tibia at about the middle of the lower third, and a fracture of the fibula at the upper part of the upper third, with a sliver of bone broken off the tibia at or near the point of fracture. This sliver could be freely moved up or down, and though the radiograph fails to show its presence, it undoubtedly existed, and notwithstanding we had two oblique fractures, this patient got well with less than an inch of shortening, but if we were guided by this skiagraph we might think that the adjustment of these bones were not as perfect as it might have been, and that there was a deformity of considerable magnitude. On the contrary, the man was young and healthy, with no injury of the soft parts, and we were enabled to put on extension and counter extension, which was followed by a plaster-of-paris cast after the edema had subsided, and almost a perfect result was obtained as far as the clinical features of the case were concerned.

I might multiply these cases, and no doubt many of you could add similar experiences where the radiograph has failed to convey to the eye the real condition of the injured part, and for this reason we question the propriety of bringing it into court until, by further experience, experimentation and improvements it can be made more accurate in its results.

The fluorometer, which has recently come to our notice, may prove to be a valuable aid in this direction, but so long as it is possible to take radiographs of a normal limb, which give the appearance of being fractured, and on the other hand, when skiagraphs are taken of fractured limbs that fail to show the existence of the fracture, we are compelled by force of circumstances to distrust its accuracy, and for that reason if for no other, we consider it a dangerous source of evidence which should not as yet be admitted by our courts.

In closing this paper we can find no better expression of our thoughts than that contained in an editorial published in the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION* July, 1897, which says, "failure of identification of these skiagraphs would destroy their legal value theoretically, but they would be none the less without effect upon the minds of the jury to whom they had been exhibited. If the X-ray is to play any part in medical jurisprudence it must be subject to the time-honored rules of evidence, which centuries of the English common law have shown to be best adapted to secure the rights of the individual."

DISCUSSION.

Dr. W. W. GRANT of Denver—This paper addresses itself to us, first, in a scientific sense, and second, in its practical relation to us as surgeons, and in order to properly appreciate its

significance we should first understand explicitly what the law requires of us as surgeons. I have investigated what the law requires and I believe the X-ray may be used just as readily against as for the surgeon. First, unless the surgeon in treating a patient in a case of malpractice, can show that he has treated him in accordance with that experience which is embodied in the ordinary text books of his profession, and the patient is dissatisfied, he is liable in pecuniary damages to his patient. If he should accept the teaching of the X-ray in any case and his results were not satisfactory, he would be liable for damages. The X-ray can be made a dangerous instrument as well as an aid to the surgeon, and if the profession treats it as it usually does everything new it will prove an instrument of danger. It will be an expensive thing for the surgeon. The X-ray is a greater aid to the surgeon in the location of foreign bodies than it is in pathology: it does not show us in the course of the reparative process of bone what the stage of that process is. It will show any bone not covered heavily by muscles, and whether it is displaced, probably, yet there are errors in that. It does not show beyond the temporary bone that is thrown out in the repair of fractures and in the pathologic lesions of bones. No supreme court has yet passed upon the admission of the X-ray in evidence. Local courts all over the country are divided on the subject. The more experienced and learned judges hesitate to accept it, and until the lawyers and the courts ask for its introduction as evidence, surgeons should not try to introduce it, and not then unless we know that it is absolutely reliable. It is different from the old photograph, about which long contests were waged in our courts, as to its admission as evidence. Even the photograph of an object, not of the shadow of the object as this is, was not admitted until the photograph itself was verified. That we can never do in the case of the X-ray except by postmortem.

While I am confident that the X-ray will be useful as an aid to diagnosis, we have not yet reached that stage in our knowledge where it can be safely relied upon to the exclusion of that clinical experience, which every trained surgeon has learned before the X-ray was dreamed of, and which will be useful at all times even in opposition to elements which we consider of scientific precision.

Dr. HOWARD J. WILLIAMS of Macon, Ga.—I have had two cases bearing on this subject that I think will be of interest in showing that the X-ray is not really of so much value to us in a surgical way as we have regarded it. The first case was that of a child, 7 years of age, that was brought to me early in April of this year. A horse had stepped on its arm, breaking it at the middle and at the wrist, forming at the lower end a Colles' fracture, the upper a compound fracture. The child was treated by a physician in a country town and he had a bad result. The family, understanding that I had an X-ray apparatus, brought the child to me and I took a photograph of the arm, and from the result I thought there was exuberant callus at the wrist. There was loss of power in both the wrist and hand. I told the parents that I thought it was not the fault of the surgeon and possibly something could be done, and that in my opinion the Colles' fracture was binding the tendons and nerves. I anesthetized the child, cut down on the wrist and found there was no union whatever, no binding of the tendons nor of the nerves. Extending the incision at the wrist I found that there had been not only a compound fracture of the bone, but the nerves and muscles had been destroyed above. In this case was fatty degeneration of the muscles above and contraction of the tendons.

The other case was that of a railroad man who had sustained a compound fracture of his hand. I photographed his hand, and found displacement of the metacarpals. In operating I found that there had been a worse destruction of the soft tissues than there was of the bone, showing that while the radiograph will give us an accurate account of bone conditions, there are also injuries of other tissues that must be counted on anatomically. We could not in either of these cases say that the injuries were due to the bone lesions.

Dr. W. J. MAYO of Rochester, Minn.—Dr. Reed, in the first operation, showed his good surgical sense in his endeavor to remove the pin from below, or the head end, as other things being equal, drawing from the point would endanger piercing important structures, and the head would be an obstacle to the removal.

A somewhat similar case was operated upon by Dr. C. H. Mayo. A loop buckle was swallowed and lodged in the esophagus of a child. It was easy to locate it by bougies at a point behind the sternum. The buckle, which was such as is used at the back of a vest, had two sharp prongs, and might be opened or closed, and if open, in which direction were the prongs? The X-ray showed that it was open and pointed to the left. A right external esophagotomy rather than the com-

mon operation on the left side was made use of, and it was hooked out by the loop. From the left side the prongs would have been forced into important structures, if not preventing its removal.

In the work of Dr. Cross of our city with the X ray, much aid has been given in the operation for removal of foreign bodies by placing a metallic object on certain prominent landmarks and fastening with adhesive straps. The foreign body is noted in relation to these objects in the picture.

In its medico-legal relations it should not be forgotten that the X-ray operator either by wilfulness or negligence in fastening the plate and making the exposure may exaggerate any existing deformity and an unprejudiced artist should be insisted upon. I have less confidence in pathologic X-ray work, such as fractures, but for foreign bodies too much praise can not be bestowed upon it.

Dr. JAMES BERRY of Chicago—I think the X-ray should not be considered as a referee in any of these questions. The information given by the X-ray is simply an aid to diagnosis depending on a good many circumstances. If a picture by the X-ray process contradicts all surgical knowledge of other symptoms given by the patient, or that part under consideration, it should not stand against all the other evidence.

I have never seen a fracture shown by the X-ray where none existed. I have read of such instances. I believe a fracture may not be shown by the X-ray when it does exist. I think the X-ray will show callus. If it does nothing else but show the presence of a foreign body, it is a good thing.

I think it is not an exaggeration to say that I have seen 5000 pictures in the last two years, taken to show the surroundings of accidents by ordinary means of photography. These means differ widely. Unless you know how they are taken, the condition of the light, the position of the camera, the intention of the operator, and a great many other circumstances, the photographs are absolutely useless. I think it is so to a greater extent in regard to the X-ray pictures, because less is known about them. The argument that the X-ray is a dangerous process to the surgeon should not stand. If it is a valuable aid it should be used. If it hurts now and then we can not help it. It certainly can not exaggerate as much as we have seen surgeons on the stand exaggerate in suite for malpractice. In a recent case a surgeon testified that he knew there was dislocation of the hip because he had put his thumb from the outside surface of the hip into the acetabulum in a patient that weighed 225 pounds. I never saw the X-ray exaggerate more than that. I think the use of the X-ray should be limited. We can not keep it out of court. Supposing we are all on the defense side, the plaintiff will bring it into court. It should have its proper limitations defined, and no one should think that the X-ray is a referee or is the final arbiter in the matter, but that it can be very useful as an aid. I think it is useful in showing that a good serviceable limb can be obtained with a great deal of deformity, and there are many ways in which it is useful.

Dr. W. L. SMITH of Streator, Ill.—I saw Dr. Berry give a demonstration in 1896 before the Chicago Medical Society. Shortly after this I procured an X-ray apparatus and I have located fully fifty foreign bodies in the arms, legs and feet of men, women and children, and have cut down and removed them with less laceration of tissue than I could have done had I not had the X-ray skiagraphs as a guide.

I have treated thirty-two cases of Colles' fractures since I have adopted the use of the X-ray, without a single untoward result. I have made skiagraphs once a week, and if any deficiencies were found, have corrected them. I am sure this could not have been done without the aid of the X-ray in fractures of the arms and legs. I think if we take a picture at least once a week and redress, if necessary, we will get better results than we otherwise could under any circumstances without the X-ray.

Dr. W. W. GRANT of Denver—The X-ray will have a legitimate place in the practice of surgery, but that place I think is not yet known. Just what that place is in medico-legal practice is not today settled. It is chiefly in the location of foreign bodies that the X-ray is of use to surgeons. When we remember that most of the foreign bodies, as lead, are aseptic, the benefits resulting from the X-ray are exaggerated. We remove more bullets on account of the X-ray, yet most of them would not have done any harm if allowed to remain. Unless pressing upon some important nerve or structure, they will be encysted and do no harm. The tendency is to exaggerate everything that is new that has in itself any real intrinsic value.

Dr. W. J. GALLBRAITH of Omaha—From the expressions of the Fellows of this Academy, I believe the time has arrived when it is our duty to take some action as regards the use or abuse of the X-ray from a medico-legal standpoint. I have

treated a number of Colles' fracture by the aid of the X-ray and have had no trouble. For us to place ourselves in a position to state that it is necessary for the X-ray to assist us in a surgical way is entirely unjust and uncalled for, for we will receive more abuse in times of tribulation from such recommendations than we can ever escape from.

Dr. THOMAS B. LACEY of Council Bluffs, Iowa—The consideration of the radiograph can not go any further than simply as an adjunct. It is very evident from the paper of Dr. Reed that it will not show the presence of foreign bodies in certain parts of the body. I refer to the gun-shot wound of the skull. There it failed to show the presence of any foreign body, though the bullet was imbedded in the brain tissue. We should not place undue reliance upon the X-ray as a means of diagnosis. I saw a skiagraph of a fracture of the leg in which there were seven distinct fragments. If you were to take that skiagraph and show it to the jury, and keep the limb itself out of the way, I have no doubt but that every man on the jury would say that the leg was not well taken care of. If that be true, it seems to me that if a skiagraph were placed before a jury it would injure the case in which the surgeon might be deeply interested. So I feel that the Academy, as well as other associations of this character, should be guarded in pronouncing the X-ray, or skiagraphs, of such vast importance until their actual value is demonstrated.

Dr. CHARLES K. COLE of Helena, Mont.—It would be unwise for us, as a medical body, to propose that the use of this method shall in any sense be the final arbiter in any case. It is useful. It has come to stay and will unquestionably be used hereafter to an extent perhaps which we do not anticipate, but it has no medico-legal aspect at this time. I doubt whether any of the lower courts or the supreme court in any part of the country would take a picture as graphic as that and pass upon a case with reference to the picture only. That depends upon the experience and judgment of the surgeon in charge, or upon the testimony on the other side.

Dr. C. B. KIBLER of Corry, Pa.—The present status pertaining to the use of skiagraphs can be very much likened to that of the medical expert. You can get medical experts for or against for a consideration. I believe skiagraphs today can be produced to misrepresent the true condition of a fractured limb, the different shapes and different positions it might be placed in, and in this way act detrimentally to the interest of the surgeon who might have a case of malpractice in court. None of us know the future possibilities of the X-ray. We hope much good will come of it, but for the present we know but little.

Dr. W. L. SMITH of Streator—I recall the case of a man who was shot in the knee and I took five different radiographs before I was able to locate the bullet. I finally located it behind the head of the tibia about an inch and a half deep. I recall also the case of a judge who was shot in a riot in 1893 or 1894. I was unable to locate the bullet in his case. It was supposed to be in the pelvis somewhere.

Dr. JAMES BERRY of Chicago—If the X-ray picture shows clearly a buck-shot in the hand that could not be diagnosticated in any other way, it would be the height of nonsense to say that the buck-shot was not there. The X-ray has its limitations, and I do not believe it is wise to give up a thing because it does not show a certain condition. I have taken a great many pictures that did not show anything that I expected to see of the conditions that were there. On the other hand, I have taken pictures showing conditions that could not be demonstrated or ascertained by other means, so that I think the X-ray is an aid to diagnosis, but that is all anyone can say.

Dr. W. W. GRANT of Denver—I would like to ask a question in reference to the point I suggested as to the use of the X-ray in giving information during the repair of bone, whether from disease or a fracture. I know the statement is very generally made and believed that the X-ray does not show anything but solid bone, that nothing is clearly defined. I have recently had an experience in a case of fracture of the lower end of the humerus, in which I have at different stages taken pictures. These pictures will convince any surgeon that the X-ray is absolutely worthless as showing the degree of repair of bone. I made passive motion of the joint that would have broken up any fracture that was not united, yet the X-ray does not show it. I know there is temporary callus. It has verified what has been stated in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, that the X-ray shows well organized bone and nothing else.

Dr. REED—There is no question in my mind but what the use of the X-ray in general practice is to a certain extent an aid, but the object of my paper was to endeavor to locate what position the X-ray should take from a forensic standpoint. This is a very important question and should be kept separate from

the practical work that we do every day, until we are certain of what is shown by the X-ray. It is true that the X-ray is an aid to diagnosis, but while it may be an aid I believe that up to the present time, if admitted to the courts as evidence, it will do more injustice than justice. In a case I have at present, the man was shot a year ago, at close range, with a thirty-two caliber bullet, which entered immediately above the pubes, missing the pubic bone. He did not feel any harm from it for some time. Some weeks ago it appears that an abscess had formed and had broken into the bladder and there was a profuse discharge of pus from it. In sounding the bladder neither myself nor colleagues were enabled to detect the bullet. There was no escape of urine at the time of the primary injury, and it would have been hardly possible for it to have remained in the bladder without causing any irritation. I suspect that this bullet is located somewhere exterior to the bladder, and that sepsis has taken place, followed by suppurative and rupture into the bladder. I am exceedingly anxious to know what the radiographer will find in this case.

From a picture, such as I have seen taken, it is impossible to tell whether there was a separation of the epiphysis from the body of the bone or not, when the facts were that there was no separation whatever. Suppose in a case of this kind a party wishes to defraud us, and should fall off a car and injure the limb slightly (probably the knee is swollen a little), and should go to a radiographer and have a skiagraph taken and exhibit it in court (although we know the man is not injured in the slightest), and there should be the appearance of separation between the epiphysis and bone, there is only one thing that we could expect the jury to say, and that is, we were mistaken and the radiographer was correct. I feel that while X-ray skiagraphs are of value in our practice, as aids to diagnosis, it is necessary for us to develop the facts better before they should be admitted to the courts as evidence, either by the prosecution or the defense.

CLINICAL SIGNIFICANCE OF THE DIFFERENT FORMS OF THE KLEBS-LOEFFLER BACILLUS.

Read before the North Chicago Medical Society Dec. 23, 1897.

BY W. J. CLASS, M.D.

ASSISTANT TO THE CHAIR OF PATHOLOGY, CHICAGO POLICLINIC, MEDICAL INSPECTOR CHICAGO HEALTH DEPARTMENT (ANTITOXIN STAFF).
CHICAGO, ILL.

It is not necessary for me to enter into a detailed description of the bacillus of diphtheria, history of its discovery, growth in different culture media etc.: a few remarks however especially in regard to its morphology will be required in order to present this paper properly. Fraenkel in his work on bacteriology describes the Klebs-Loeffler bacillus as a bacterium, resembling in many respects Fraenkel's diplococcus of pneumonia. According to him, their habitat is in the oldest part of the pseudo-membrane. They are little rods of moderate size, usually slightly bent, about as long as the tubercle bacillus but twice as broad, hence of a rather coarse appearance and usually with rounded ends. But the form of this micro-organism is exceedingly variable, and the differences are striking in appearance. The bacteria are sometimes seen enveloped in a more or less capacious glassy membrane: sometimes the contents separate into several pieces divided by a broad transverse wall: one end of the rod is very frequently thickened like a club; sometimes this change appears on both ends so that there will be dumb-bell shaped structures, usually pointed out as involution forms. The bacilli are immobile, have no spores, perish rather rapidly when dried and succumb at 45 to 50 degrees C. They stain with difficulty, the terminals staining better and therefore standing out as dark spots from the pale center. In recent cases they are usually found associated with streptococci. Martin, in 1892, describes three forms of the Klebs-Loeffler bacillus, as being of comparatively constant occurrence in different cases of diph-

theria, namely, long entangled forms, medium sized bacilli arranged parallel and short parallel bacilli. Other authors have made different classifications, which, however, amount to about the same.

The significance of these different morphologic varieties, and the import of the almost constant occurrence of the streptococcus, especially in severe cases, are the chief points to be considered in this paper. E. A. Peters of London, in an article in the *Journal of Pathology and Bacteriology*, claims the long bacillus is the more constantly present and gives rise to a more severe type of the disease than the shorter form, which is of rare occurrence. He does not seem to attach much importance to the streptococci. His examinations, from which he draws these conclusions, were made from bacteria grown on different culture media instead of from slides made directly from the throat. As the size of the bacilli grown on the different culture media varies considerably, those grown on blood serum being larger than those grown on agar-agar. I do not consider his statistics quite reliable. On the other hand, Cornil and Babes in their text-book describe a long pseudo-bacillus, which occurs in mild cases and is considered, by them, to be an involution form of the true Klebs-Loeffler bacillus. Jacques of Chicago, in an article read before the Chicago Medical Society, makes the following statement: "In the early autumn the bacilli are small, producing a small amount of membrane and involving the cervical glands; little or no temperature and great malignancy causing the patient to be stupid as if under the influence of a strong narcotic. As the winter progressed this type changed. The bacilli became larger, more membrane was formed and the type was pharyngeal, with occasional involvement of the larynx." This statement, in general, agrees with my experience except that I have not noticed any change in the size of the organism as the season advanced, but have found the short bacillus, usually associated with the streptococcus, almost invariably in the severer forms of the disease.

In the cases of which I have kept a record and which I quote, the bacteria I mention were found in the material derived directly from the throat of the patient, a culture being made later in each case to verify the findings.

Case 1.—F. S., aged 3, third day,¹ had extensive membrane in pharynx. No antitoxin was used, death from toxemia fifth day of disease. Short Klebs-Loeffler bacillus and streptococci were found.

Case 2.—C. B., aged 20, fifth day, small amount of membrane in pharynx, larynx slightly affected, severe general intoxication, 5500 units antitoxin used, recovery. Short Klebs-Loeffler bacillus and streptococci were found.

Case 3.—A. M., aged 2, third day, small amount of membrane in pharynx, larynx, trachea and probably also in bronchi. Intubation was done without affording relief, 2000 units antitoxin used, death same day. Short Klebs-Loeffler bacilli and streptococci were found.

Case 4.—G. F., aged 8, second day, membrane in pharynx and tonsils, constitutional symptoms moderate, 1500 units antitoxin used, recovery. Typical Klebs-Loeffler bacilli and staphylococci were found.

Case 5.—E. C., aged 15, second day, small amount of membrane on tonsil and uvula, 2700 units antitoxin used, constitutional symptoms mild, recovery. Strepto- and staphylococci were found.

Case 6.—C. P., aged 9, third day, small amount of membrane in pharynx, constitutional symptoms moderate, 1700 units antitoxin used, recovery. Typical Klebs-Loeffler bacilli were found.

Case 7.—R. P., aged 8, fifth day, extensive membrane on

¹ In these cases the day referred to means the one on which first examination was made. The symptoms are those observed during entire course of the disease.

tonsils and uvula, constitutional symptoms of moderate severity, 2000 units antitoxin used, recovery. Typical Klebs Loeffler bacilli and streptococci were found.

Case 8.—C. S., aged 3 years, six months, fifth day, involvement of larynx and pharynx, constitutional symptoms severe, 1500 units antitoxin used, recovery. Short Klebs-Loeffler bacilli and streptococci were found.

Case 9.—A. C., aged 3, fifth day, laryngeal type with severe general symptoms, 3000 units antitoxin used. Short Klebs-Loeffler bacilli and streptococci were found.

Case 10.—F. N., aged 8, second day, laryngeal type, pharynx only reddened, constitutional symptoms of moderate severity, 1000 units antitoxin used, recovery. Typical Klebs Loeffler bacilli and streptococci were found.

Case 11.—H. B., aged 13, second day, small amount of membrane on tonsils, general symptoms mild. Long Klebs Loeffler bacilli were found.

Case 12.—A. H., aged 6, third day, small amount of membrane in pharynx, general symptoms of moderate severity, 2000 units antitoxin used, recovery. Long Klebs-Loeffler bacilli were found.

Case 13.—K. L., aged 6, second day, small amount of membrane in tonsils, general symptoms mild, 1000 units antitoxin used, recovery. Streptococci and micrococcus tetragenus were found.

Case 14.—J. M., aged 8, second day, extensive membrane in pharynx and tonsils, constitutional symptoms moderate, 2500 units antitoxin used, recovery. Typical Klebs-Loeffler bacilli were found.

Case 15.—L. M., aged 12, second day, slight amount of membrane on tonsils, general symptoms mild, 1500 units antitoxin used, recovery. Long Klebs-Loeffler bacilli were found.

Case 16.—A. N., aged 5, second day, small amount of membrane in pharynx, general symptoms mild, 1500 units antitoxin used, recovery. Long Klebs-Loeffler bacilli were found.

Case 17.—G. L., aged 4, fourth day, extensive membrane in pharynx, constitutional symptoms of moderate severity, 1000 units antitoxin used, recovery. Typical Klebs-Loeffler bacilli were found.

Case 18.—P. L., aged 5, second day, extensive membrane in pharynx, constitutional symptoms of moderate severity, 1000 units antitoxin used, recovery. Typical Klebs-Loeffler bacilli were found.

Case 19.—A. L., aged 1, first day, redness and white spots on tonsils, constitutional symptoms of moderate severity, 500 units antitoxin used, recovery. Typical Klebs Loeffler bacilli were found.

Case 20.—E. D., aged 12, second day, fairly extensive membrane in pharynx, constitutional symptoms of moderate severity, 1500 units antitoxin used, recovery. Typical Klebs-Loeffler bacilli and streptococci were found.

Case 21.—S. D., aged 8, first day, redness and few white spots in pharynx, general symptoms of moderate severity, 750 units antitoxin used, recovery. Typical Klebs-Loeffler bacilli and streptococci were found.

Case 22.—G. P., aged 8, fifth day, extensive membrane in pharynx, general symptoms severe. 2000 units antitoxin used, recovery. Short Klebs Loeffler bacilli and streptococci were found.

Case 23.—H. B., aged 4, first day, redness of tonsils and pharynx, general symptoms mild, 1000 units antitoxin used, recovery. Long Klebs-Loeffler bacilli were found.

Case 24.—M. K., aged 17, second day, moderate amount of membrane on tonsils, constitutional symptoms moderate in severity, 1500 units antitoxin used, recovery. Long Klebs-Loeffler bacilli were found.

Case 25.—R. L., aged 5, third day, moderate amount of membrane in pharynx, constitutional symptoms severe, 2000 units antitoxin used, recovery. Short Klebs Loeffler bacilli and streptococci were found.

Case 26.—M. R., aged 4, second day, small white patches on tonsils and uvula, general symptoms mild, 500 units antitoxin used, recovery. Pseudo Klebs-Loeffler bacilli were found.

Case 27.—G. C., aged 10, third day, extensive membrane in pharynx, constitutional symptoms of moderate severity, 1500 units antitoxin used, recovery. Typical Klebs Loeffler bacilli and streptococci were found.

To sum up: We have seven cases with severe constitutional symptoms, with two deaths; in all of these the short Klebs-Loeffler bacillus and streptococci were found; thirteen cases in which the constitutional symptoms were not so marked, but the membrane was, as a rule, thicker and more extensive; in six of these typical Klebs-Loeffler bacilli were found alone, in five

they were associated with streptococci, and in one each are found typical Klebs-Loeffler bacilli with staphylococci and long Klebs-Loeffler bacilli, respectively. In the remaining seven cases the constitutional symptoms were mild or entirely absent; of these, four showed the presence of the long Klebs-Loeffler bacillus alone, and, in one each, streptococci and staphylococci; streptococci and micrococci tetragenii, and pseudo Klebs-Loeffler bacilli were found.

As the result of these examinations I have arrived at the following conclusions:

1. That the short Klebs-Loeffler bacillus apparently produces a toxin of greater virulency than the longer forms, although the local manifestations may not be so extensive.

2. That the long Klebs-Loeffler bacillus and the streptococci when found alone give rise to a mild type of the disease.

3. That the streptococcus is found associated with the Klebs-Loeffler bacillus in most of the severe cases. Its special significance is not so clear, but it is possible that by causing a more intense inflammatory reaction it opens avenues by which the toxins of the Klebs-Loeffler bacillus may find more ready entrance into the circulation, plus its own toxin.

4. That the apparent beneficial action of the antitoxin of the Klebs-Loeffler bacillus in cases where this bacillus is not present, may be due to the fact that though the local action of the different microbes varies to a considerable extent, the action of their toxins, as is shown by the similarity of the constitutional symptoms produced by them, present many kindred features. The thought, therefore, arises that the antitoxin of one infection may have an inhibitory effect on the toxin of another, as is shown by the fact that whooping cough and some other infectious diseases have been shown to occur less frequently in vaccinated persons and some cases have, apparently, been cured by vaccination.

NOTE.—By the term typical Klebs-Loeffler bacillus is meant the medium sized bacillus as described by Martin.

TETANUS; ANTI-TETANIC SERUM; REPORT OF CASE.

Read before the Winona County Medical Society, July 6, 1897.

BY HUGH F. MCGAUGHEY, B.S., M.D.

WINONA, MINN.

Tetanus is a toxic infection dependent on the products of a specific germ. It is spoken of as traumatic when the infection takes place through a recognized wound. In idiopathic tetanus the infection atrium is some unnoted lesion. It is possible that the germs may sometimes find entrance through mucous membranes. Infection after labor gives rise to puerperal tetanus. Trismus neonatorum occurs as a rule through inoculation of the umbilicus. Tetanus cephalicus sometimes results from wounds of the head, the symptoms being limited to this region.

The bacillus of tetanus was first described by Nicolaier, in 1884. He obtained it from wounds and from the soil. Five years later Kitasato secured it in pure

culture. The germ itself is not tenacious of life. It is strictly anaerobic, oxygen preventing its growth. Under favorable conditions spores form in one end of the rod-like germs, giving them a characteristic drum-stick shape. The spores are very resistant to destructive influences and are widely distributed in the soil, dust, etc. They are the usual source of infection.

It is evident from their common occurrence that the spores must find entrance to many wounds in which they do not develop. Free access of oxygen would prevent this and punctured wounds are, therefore, especially dangerous. Recent experiments in inoculating animals with spores obtained from pure cultures and freed from toxins show that they do not develop unless there be present certain additional factors, such as bruising of the tissues, effusion of blood, or mixed infection with other germs.

The ordinary antiseptic solutions are not effective in destroying the tetanus spores, requiring a contact of several hours, and in general they will not destroy the toxins. Sodid or potassic hydrate in 0.3 to 0.4 per cent. strength are recommended in addition to ordinary antiseptics. Iodin solutions, either 0.5 per cent. iodid trichlorid, or solutions of iodid with potassium iodid are especially effective in destroying both spores and toxins. (Kitasato, cited by Lambert.)

A number of ptomains and a toxalbumin have been obtained from tetanus cultures, but the chemic nature of the real poison has not yet been definitely determined. A concentrated poison has been obtained of such strength that the estimated fatal dose for a man is 0.23 mg., or about 1/250 gr.

The germ, when it develops in the body, multiplies in the vicinity of the point of inoculation, but does not become generally distributed. The blood absorbs the toxic products, which thus reach the nervous system and produce their characteristic effects. The blood of tetanus patients is toxic for animals when injected into the circulation. The toxins have been recovered from the urine. The postmortem findings of various observers differ, but lesions have been noted in the spinal cord; particularly changes in the nerve cells of the motor horns. Pitfield (*Therapeutic Gazette*, March 15, 1897), has employed a weak tetanus toxin therapeutically as a stimulant to the cord, in one case of mixed spinal sclerosis with apparent benefit.

The antitoxin of tetanus was introduced by Tizzoni and Cattani of Bologna. The preparation of this antitoxin is similar to that of diphtheria. Horses are injected with a tetanus toxin obtained by filtering pure cultures of the bacillus. Beginning with a dose of 0.5 c.c., the dose is gradually increased until the animals bear from 700 to 800 c.c. After several months a high immunizing power is thus obtained. The blood is drawn and the serum separated. The serum may be used for injection, or the antitoxin may be precipitated by alcohol and obtained in a dry form to be dissolved for use.

The antitoxin is said to be perfectly satisfactory in the laboratory. A definite quantity absolutely protects animals when given at the same time with the previously determined fatal dose of the toxin. The proportion of antitoxin required for a given toxin may be mathematically determined.

The application of the remedy meets many practical difficulties. There is no means of estimating the amount of toxin in the system and by the time clinical evidence of infection is obtained irreparable

damage may have been done by the poison. Again, experimentally the quantity of antitoxin necessary to protect increases rapidly with the length of time elapsing after the injection of the toxin. Behring has estimated that the amount required to save an animal twenty-four hours after giving a fatal dose of the toxin would be impracticable of administration, on account of its bulk. The chances of employing the remedy clinically before the absorption of dangerous quantities of the poison are not nearly so favorable as in diphtheria.

The antitoxin has been employed as a prophylactic both in medical and veterinary practice. Its use is reported in a considerable number of cases in localities where tetanus is common. Tetanus failed to develop in all the cases. Of course there is no means of knowing whether infection was present.

The antitoxin acts not by destroying or chemically neutralizing the toxin, but by rendering the system immune to its action.

Lambert (*New York Medical Journal*, June 5, 1897) gives the statistics of 114 cases of tetanus treated by antitoxin, with a mortality of 40.35 per cent. Excluding deaths within twenty-four hours after beginning treatment and deaths from intercurrent disease; excluding also recoveries in mild cases not treated before the tenth day of the disease, leaves seventy-one cases, with a mortality of 29.57 per cent. Of these, thirty-one cases, with an incubation of eight days or less, are classified as acute and give a mortality of 61.29 per cent.; forty cases occurring after a longer period and classed as chronic, give 5 per cent. mortality. For comparison, in a collection of 1502 cases of all sorts treated without antitoxin the mortality was 87.7 per cent. Lambert considers a fairly low estimate of the death rate to be 80 per cent. for acute cases and 40 per cent. for chronic cases. This is certainly a very favorable showing for the antitoxin.

Case.—W. S., aged 23, steamboat hand, alcoholic, attempted to board a moving freight train May 1, 1897. He fell and sustained injuries which necessitated amputation of the ring and little fingers of his right hand. The end of the middle finger was lacerated and received two stitches. A wound of the scalp also required sutures and there was an extensive abrasion of the forehead. He was attended to in the office under ether anesthesia. Alcohol and bichlorid solution (1 to 1000) were freely used in cleansing the wound areas, which were very dirty. Some suppuraton developed in the end of the middle finger and in one corner of the stump of the ring finger. The other wounds healed promptly without pus. On May 18 the wounds were last dressed, all being dry and apparently in good condition. Patient was in a state of moderate alcoholic exhilaration on this date. He complained of no unusual symptoms, although his history showed later that such were present at this time.

Three days after this he sent word that he was sick. He was found in bed, complaining of great pain in the abdomen and back. His spinal column was perfectly rigid. His masseters were contracted and the jaws could not be separated over half an inch by force. He received morphin by mouth and was removed two hours later to the Winona General Hospital. He could get out of bed only by turning on his face and dropping his knees to the floor, the stiffness of the back preventing his rising in the ordinary manner. He walked downstairs with great difficulty, the exertion being attended with general clonic spasms.

On admission to the hospital at 4 p.m., his axillary temperature was 99.5, pulse 84, regular. The facial muscles were contracted and prominent, the corners of the mouth somewhat elevated, the masseters rigid. The muscles of the neck, back and abdomen were in a state of tonic contraction. Opisthotonos was not marked. Breathing was shallow. The arms were moved freely, but there was some stiffness of the legs and tremor when they were lifted from the bed. The tongue was heavily coated and the breath foul. He complained mainly of spasmodic pain referred to the epigastrium, and suffered from painful muscular contractions in the throat on swallowing.

His history was gathered from time to time, as talking was difficult. On May 16, five days before admission, he noticed soreness of the jaw muscles and twitching of the face. On the following day the legs became stiff and jerked at times while walking. The intermittent pain in the epigastrium next appeared. The jaws became stiff and walking was difficult. The day before admission was spent in bed. Patient had been living irregularly and had slept in a barn on one night. He at first supposed symptoms to be the result of taking cold. The wounds all appeared in good condition and offered no evidence as to the site of the tetanic infection, hence no indication for local treatment could be determined.

Patient was placed in a darkened room and 10 c.c. of antitetanic serum was injected in the back with antiseptic precautions. This dose was repeated in four hours and again nine hours. Chloral, in 0.97 gram doses, every four hours, was given at night, and potassium bromid, 1.3 gram every three hours, by day, to secure rest and quiet. A few hypodermics of morphin were used at long intervals for pain. The bowels were freely moved by 0.32 gram of calomel. No difficulty in urination was experienced. Patient was able to swallow liquids with some difficulty. He slept a considerable portion of the time. On awakening or when startled there was jerking of the limbs. The tongue and cheeks were repeatedly bitten by involuntary closure of the jaws. The temperature was 99 in the axilla on the second day, but did not again reach this point.

The symptoms progressively but very gradually improved. By the third day the muscular contraction was noticeably diminished and the pains less severe. A week later he could sit up, and two weeks after admission he left the hospital walking fairly well, though complaining of some stiffness. Since then he has not reported.

After receiving the third dose of serum the pulse was noticed to be extremely intermittent and irregular. Its rate varied at times from 60 to 120 a minute, especially after any exertion. This condition persisted for about a week. There was no evidence of disease of the heart. It seems unlikely that this condition could be produced by the moderate doses of the sedatives used. No local reaction, or skin or joint symptoms followed the use of the serum.

It is not possible to draw any very valuable inferences as to the effect of the serum from a case of this nature. The length of the incubation (fifteen days), and the slow onset of the symptoms place it with the chronic type of tetanus and make the prognosis relatively favorable. It is difficult to say what effect, if any, the serum had on the course of the disease. It is certain that the striking results obtained by some observers were not in evidence. However, the beginning of a gradual improvement at a time when the symptoms were progressively increasing in severity coincided with the injections. It would appear that in an acute case the dosage here employed would be quite inadequate.

DISEASES OF THE MASTOID, THEIR COURSE AND TREATMENT.

BY FRANK S. MILBURY, M.D.

Otologist, Ophthalmologist and Laryngologist to the Bedford Dispensary and Hospital and the North Brooklyn Eye, Ear and Throat Hospital.
BROOKLYN, N. Y.

Before beginning the consideration of this paper, I wish to request your attention for a few moments to some of the anatomic features of the middle ear and mastoid.

It is in an air-containing space, lined throughout with mucous membrane, and continuous with the covering of the naso-pharynx and adjacent parts. Its divisions are the eustachian tubes, the tympanic cavity, and the mastoid cells. The first is the channel of connection between the pharynx and the tympanum and consists of two portions, the cartilaginous and osseous, the widest opening being pharyngeal and its

narrowest point at the junction of the soft and the bony part. It is from one inch to one and one-third inches long, the osseous forming about one-third of its length, and the two portions are formed at an obtuse angle. Its direction is obliquely outward, backward and slightly upward. The tubal mucous membrane contains throughout a ciliated epithelium destitute of glands, the movements of the cilia being from the tympanic cavity, thus aiding in the drainage of the tympanum, and partially preventing its invasion by pathogenic organisms from the rhino-pharynx.

The tympanic cavity is an irregular pneumatic shaped space with its longest diameters vertical and lateral, containing the ossicula and consists of two portions, the atrium immediately behind the membrana tympani, and the attic which lies above the membrane. The communication between these two is quite narrow owing to the arrangement of the ossicles and folds of mucous membrane, and therefore a slight inflammation and swelling of the tissues may easily shut off the attic space, producing interference with its drainage, this being a serious factor in middle ear pathology. The mucous membrane lining the tympanic cavity is thin and delicate and closely adherent with the underlying bone; its epithelium is usually tessellated, and may in places be ciliated, the latter being found most frequently in the vicinity of the eustachian orifice. A little above, continuous and posterior to the attic, the mastoid antrum is situated, and is the only pneumatic space developed at birth, the others being formed subsequently. Not infrequently a second cell of considerable size is found at the tip of the process. The mastoid process, both externally and internally, varies greatly in its construction; thus, we may have those which are entirely pneumatic, those which are pneumatic and diploetic, those which are wholly diploetic, and, lastly, those which are altogether sclerotic excepting the antrum. Zuckerkandl, in the examination of 250 bones, found 36.8 per cent. completely pneumatic, while 42.8 per cent. were mixed diploetic and pneumatic, and 20.4 per cent. entirely diploetic or composed of dense osseous tissue throughout. These conditions are also found to vary on the two sides, one side being partly pneumatic and the other completely so. From such examinations it is evident that a sclerotic process does occur normally as well as the result of inflammatory action. The position of the lateral sinus varies greatly in different individuals, sometimes being an inch or more posterior to the wall of the meatus, and, again, the bend of the sinus is so sharp that it extends forward so near to the posterior wall of the meatus that the opening of the antrum would be impossible without wounding this venous channel. To the operator the position of the sinus and the middle cerebral fossa is of special importance, and many efforts have been made, by the examination of specimens, measurements of the skull and its outward conformation, to determine the location of the sinus; but all such researches have proven useless. Dr. Politzer states that in about 500 temporal bones which he examined he found the position of the sinus most favorable when the mastoid process was strongly developed, and entirely filled with pneumatic cells. In these cases there is a broad space between the sigmoid sinus and the posterior wall of the external meatus, which, in operating, permits access to the antrum without danger of wounding the sinus. He found the relations less favorable in the diploetic and com-

pact mastoid processes. How are we to know positively whether the process is diploetic or pneumatic? Hence, for practical purposes these investigations prove as useless as others.

We will now consider the individual mastoid diseases.

Primary mastoiditis is very rare, and when it does occur is usually the result of traumatism or exposure, but sometimes without any traceable cause; the latter usually found in persons of a cachectic condition. Only a few cases have been reported.

Secondary periostitis, however, is quite frequent, and is due to acute or chronic middle-ear suppuration or necrosis; the process extending outward from the tympanum until the mastoid covering is reached. It occurs oftener in adult than early life, owing to the much greater liability to ear disease. In acute middle-ear suppuration it is most frequent when free drainage is interfered with, as from a very small perforation badly placed, or from a possible pus retention by blocking up the opening with powders, as boracic acid, alum and some of the more adhesive new products. The fluid must find exit, and will do so at the point of least resistance. This may be: 1, through the external mastoid cortex or into the external meatus; 2, through the digastric fossa; 3, through the roof of the antrum or the tympanic wall into the middle cranial fossa; 4, into the posterior cranial fossa, by rupture usually, into the groove lodging the lateral sinus.

If the cranial cavity is invaded meningitis is induced and may be diffuse or circumscribed. In the latter the limit appears to be caused by the formation of an epidural abscess, the infectious material being walled in all sides by adhesions between the dura and adjacent walls. Internal rupture may occur, or the free anastomosis between the blood vessels and the dura and the pericranium may provide the channel through which the infectious material may pass to the brain, producing an intracranial abscess or a thrombosis of the lateral sinus. Unfortunately these lesions often occur simultaneously, thus greatly increasing the danger to life.

Until within a comparatively recent period, the operation for acute disease of the mastoid was the principal surgical operation upon the ear. It was near the end of the fifteenth century that Piolanus proposed opening the mastoid cells; later, about the year 1655, Sir Thomas Brown advised against such a procedure; and it was not until 100 years later that the operation was first performed by Petit for the removal of secretions. In 1776 Jasser performed the operation for necrosis of the bone with great success, but, after his death, surgeons lost sight of the true indications for operating, and perforated the bone for various purposes, until the death of Bergen, a noted Danish surgeon, upon whom the operation was performed for the relief of deafness, and ended in fatal meningitis. This caused the procedure to fall into disrepute, and nearly a century elapsed before it was revived by Forget (1849), Pollin and Troeltach (1858).

When there was inflammation, swelling and tenderness over the mastoid, Troeltach made an incision down to the bone to prevent necrosis, and if the symptoms indicated a deeper seat of the disease he perforated the bone with a blunt probe. To prevent injury to the brain or lateral sinus, he placed the instrument on a line with the meatus, and worked it forward and inward in a horizontal plane. If the cortex was thick

he used a small trephine. The sinus was kept open by means of a piece of gauze.

To Schwartze is due the credit of developing the operation; by 1883 he had reported 100 cases, which was the largest number reported up to that time.

Acute inflammation of the mastoid cells vary according to the stage in which the patient comes under observation. Acute otitis media without perforation is often accompanied by symptoms of mastoid irritation, which usually subside with slight antiphlogistic measures. In acute inflammation of the mastoid cells the prominent symptoms are, 1, intense continuous pain over the mastoid and radiating over the side of the head and in the neck, which is increased on pressure and percussion, redness, heat and edema of the skin. When the abscess becomes localized the pain generally remains fixed at one point; 2, the membrana tympani appears strongly bulged forward before the pus perforates; following perforation a nipple-like projection is often found in the posterior-superior quadrant of the membrane, on the tip of which the perforation is situated; 3, a swelling and bulging of the posterior-superior wall of the canal, causing a narrowing of its lumen, and shutting from view all or a part of the membrane. These two latter points are very indicative symptoms. Free discharge from the ear exists, which rarely ever ceases while the mastoid inflammation continues. However, the only absolutely positive sign of a mastoid abscess is pus found within its interior on opening. The temperature usually ranges from 99.5 to 103 degrees, but seldom higher.

The course of the affection varies considerably in different cases; in some running to a fatal termination in a few days, and in others occupying weeks and months and possibly years to indicate positive symptoms. In chronic otitis media purulenta the extension to the mastoid is often without characteristic symptoms. The quality and quantity of the discharge varies greatly, now very slight, now copious, according as to whether there is a narrow or free outlet for drainage from attic and antrum. A thickened cheesy pus may exist for a long time in the mastoid cells without any symptoms except a stubborn, fetid otorrhea, resisting cure in spite of thorough cleansing of the tympanic cavity. We may be almost sure of retention of pus in the antrum, provided caries of the external canal, ossicles or walls of the tympanic cavity may be excluded.

Inflammation of the mastoid process and fever only occur through traumatism or the retention of pus in the cells. They may subside only to reappear. Sharp pain on pressure, united with edema, may have existed a long time without producing any perceptible change of periosteum and the bone surface. If the bone is greatly sclerosed and very dense, and the cortex much thickened, which may be congenital or occur as a result of chronic middle-ear suppuration, such acute symptoms may never arise, even in a long course of the disease. However, the absence of the same can not be looked upon favorably as a prognostic sign, for it is often just such cases that prove rapidly fatal through pyemia. Zaufal and others have called attention to the frequent existence of optic neuritis, neuro-retinitis and choked disc, in inflammation of the mastoid process, at times bilateral, at times unilateral, and not always on the affected side. The course of the morbid process in bone affection varies in different cases. Extension of the inflammation in

an outward direction, with periostitis and abscess, is the most common course. Several such abscesses, in more or less rapid succession, over the mastoid process, are indicative of disease of the bone. Occasionally the pus finds its way down the side of the neck, and forms a swelling of considerable size; or, it may pass forward to the side of the pharynx, and downward even as far as the pleura; or, it may extend into the cranial cavity, and cause trouble in the lateral sinus, or involve the Fallopiian aqueduct and the membranes of the brain.

Next to opening through the cortex of the mastoid, the most frequent point is through the posterior-superior wall of the external canal. If not recognized early it may cause such excessive bulging of the canal wall as to prevent free discharge. If seen at the proper time a generous opening followed by copious syringing may suffice to empty the mastoid process of all deleterious substances, such as pus, cholesteatoma, the cheesy exudate, epidermic masses, and even sequestra if very small. Bozold has well described those uncommon cases as mentioned above. When rupture takes place toward the digastric groove, or on the median surface of the mastoid process, and owing to its deep position beneath the fascial, the pus easily finds its way into the deep sub-muscular tissues, and along the course of the large vessels, which causes the swelling in the side of the neck with abscess formation. In the early stages no perceptible difference may be seen between the sound and diseased side. After the swelling beneath and each side of the sterno-cleido-mastoid muscle has developed, deep pressure over the tip of the mastoid elicits acute pain. An early recognition of the condition is necessary since from the consolidation of the parts invasion of the cranial cavity is likely to occur. In favorable cases the carious and necrotic portions are exfoliated, the granulation tissue is absorbed, and healing takes place. Several good recoveries have been reported, even after the whole of the mastoid process has been exfoliated. Again only small portions of bone may be detached, and fistulous openings may remain indefinitely or until properly attended to.

The prognosis in these cases of mastoid disease varies with the cause, extent and severity of the affection and with the general health of the patient. Following an acute otitis media, and promptly attended to, the prognosis is usually favorable, but in some such cases the advance may be so rapid as to baffle all our efforts to check it. It is unfavorable in tuberculosis, and in chronic purulent otitis with pent-up secretions, when the case has been neglected, and gives a history of intermittent febrile attacks, and several previous attacks referable to the mastoid region which have disappeared spontaneously or under palliative measures. The prognosis is always serious whenever there are symptoms of extension of inflammation to the membranes of the brain. Attacks of partial or complete unconsciousness, restlessness and feverishness, are of extremely grave import when occurring in a person suffering from disease of the mastoid process.

In the treatment, if the case is seen early, an attempt should be made to abort the attack by antiphlogistic measures. If the membrana tympani appears greatly congested, swollen and bulged outward, simultaneously with pain in the mastoid process, which is increased on pressure, a paracentesis of the membrana tympani should be made at once to permit the pus in

the middle ear a free exit; and in a spontaneous rupture, when necessary it must be enlarged. After free drainage has been obtained, frequent antiseptic irrigations should be instituted and carried out faithfully. A brisk purge should be administered. The application of cold to the mastoid by means of the ice-bag, iced cloths, or, what is better, the Leiter coil. The ear may be syringed with the apparatus in place. It is better to keep the coil in position continuously for twenty-four hours, and under no condition should it be kept on more than from forty to fifty hours. Painting with iodine, application of leeches, and rest in bed. In influenza cases the Leiter coil does not appear very effectual in stopping the formation of abscesses. Cold is usually very soothing and borne well. Often the pain will entirely disappear through these means while the patient is in bed and quiet, but on exertion in his duties they return. And thus it is said by some writers that if marked improvement has not occurred within forty-eight hours, operation treatment will be necessary subsequently if not at once. If abortive measures have not been successful, then operative interference must be resorted to and the following are symptoms as laid down by Politzer and others generally recognized as indicating the operation:

1. Painful inflammatory infiltration of the covering of the mastoid process, especially if an accompanying narrowing of the meatus, or obstruction of the tympanum by granulations, renders it probable that a septic condition exists in the mastoid process. The operation becomes imperative when there is high fever and signs of meningeal irritation, and when the symptoms in the mastoid process have repeatedly occurred and resisted all antiphlogistic treatment.

2. Spontaneous pain in the mastoid process, increased by pressure and accompanied by bulging of the posterior-superior wall of the meatus.

3. Persistent or occasionally remittent pain in the mastoid process, with marked tenderness, even if there be no swelling of the external integument, and no apparent obstruction to the escape of discharge from the tympanic cavity.

4. When cholesteatoma existing in the tympanic cavity can not be removed, or after its extraction with the malleus and incus the condition is not improved by careful irrigation.

5. Fistulae in the mastoid region and gravitation abscesses below it.

6. Extensive caries and necrosis of the posterior osseous wall of the meatus.

7. In all cases of middle ear suppuration, during which symptoms of meningeal irritation or of incipient sinus-phlebitis make their appearance.

8. Continued septic suppuration in the attic, the symptoms remaining unchanged after removal of the malleus and incus and several months energetic treatment, even if there are no general symptoms excepting an offensive otorrhea.

9. Pain in the mastoid process developing in certain rare cases of connective tissue hypertrophy, in osteo-sclerosis, and in osseous scars after the healing of a mastoid operation.

The operation.—A few hours before the operation the patient should be given a thorough bath, the parts within a radius of three or four inches of the ear carefully shaved and, if a man, the beard removed; then the whole side of head and neck energetically washed with soap and water, rinsed with sterilized water and

rubbed with ether to remove all oily substances. The ear is syringed with a solution of bichlorid of mercury (1 to 1000) and a wet dressing of the same is applied over the entire field of operation until the patient is anesthetized.

The antiseptic dressing is removed and the parts again cleansed with bichlorid and ear tamponed. All instruments are sterilized by boiling, and the hands and dress of the operator and assistants should receive the same careful attention as is demanded in all surgical operations. To some all these precautions may seem unnecessary, but when doing a mastoid operation the surgeon never knows what he may be compelled to do, as through anomalous positions of the parts, or to extensive necrosis, the cranial cavity may be entered, either accidentally, or he may find it necessary to extend the operation to these parts.

The incision through the soft parts should be made from the tip of the mastoid and carried upward in a curved line one-fourth inch posterior to the insertion of the auricle and to its upper attachment. It is better to make the cut, if possible, with one sweep of the knife. This is practically what is known as Wilde's incision, and has been greatly overestimated, as it is only admissible in children where the cortex is very thin and may be opened by firm pressure of the knife or sharp curette, or pus may find an outlet. In the adult, however, experience has taught all operators that it is not advisable to stop here, as the cortex is too dense and non-permeable. It certainly is not wise to do this and delay to ascertain what further may develop, and subject the patient to a second operation when it should have been completed at first. Dench states that the division of the soft parts within the meatus over the mastoid practically meets all the indications of external incision. Next, elevate the periosteum, pushing the entire flap forward. The bleeding vessels should be taken up with artery forceps, or ligated. The parts are held back with retractors so that a good view of the posterior and superior margins of the bony canal are distinctly seen and the whole field of operation laid bare. The bone should be carefully examined for fistulae or carious spots, which, if found, will serve as a guide for entrance into the bone. If none are found we proceed to open into the antrum, which is just behind the posterior margin of the meatus and just below its superior margin. Until entrance has been gained to the antrum the opening through the cortex should never extend above the superior wall of the meatus, and keep close to the posterior wall, thus avoiding the middle cranial fossa and a possible wounding of the lateral sinus, which may be misplaced. The cortex is best removed with a broad chisel and mallet, which is held parallel to the surface of the skull and the bone is cut away in thin broad chips, the opening extending inward and forward and gradually lessening in size until the antrum is reached. This never lies less than a half inch below the surface, although large pneumatic spaces may be found near the surface, which may lead us astray unless we are cautious. To prove it bend a probe at the tip and pass it downward, forward and inward for a distance of three-fourths of an inch or more, at which depth it should pass into the tympanic cavity; thus we know that the antrum has been reached and passed through.

Having gained a free entrance to the antrum, any particles of bone, cholesteatomatous masses of granulations, must be removed and the opening to the mid-

dle ear freely curetted and enlarged to give sufficient drainage. We read of cases where after penetrating to the extreme line of safety (about five-eighths of an inch) and no antrum is reached, the operation is abandoned. This need never happen. After cutting to the usual depth without finding the cavity, the rule should be adopted to direct our canal more forward so as to bring its apex over the meatus, when we can easily chisel into the attic. The membranous meatus may be dislodged from the posterior wall and pushed forward, or the entire cartilaginous meatus turned out, thereby making entrance to the attic quite easy. The latter method will apply to a sclerotic process. If after entering the antrum no pus is found, the large cell at the apex of mastoid must be particularly investigated, all carious and necrotic bone removed from mastoid and its tip excised, if carious.

The operation should be continued until sound bone is encountered in every direction. If the inner plate is diseased it may be removed with almost perfect safety, as an exposure of the dura is not a grave matter under proper precaution, whereas to leave carious bone at this point is very dangerous. Exposure or even a wound of the lateral sinus, either accidentally or intentionally, is not so serious a matter as has heretofore been considered. It can be recognized by its bluish gray color. If the vessel is opened sharp hemorrhage ensues, which if easy of access, may be readily controlled by a firm compress of iodoform gauze held by an assistant, and the operation is proceeded with as if this had not happened.

The good effects of opening the mastoid antrum and cleansing the middle ear is often manifested within a few hours after the operation. The pain and temperature are both diminished; alarming symptoms subside, while the state of the middle ear rapidly improves. Subsequent to the operation where the septic suppuration continues after weeks or months of careful treatment, there is probably a carious affection of the tympanic cavity or ossicula. If lumps of epidermis repeatedly appear in the irrigating fluid it is certain that there is a cholesteatoma in the attic, which indicates an operation on the tympanic cavity, described later.

Having completed the operation, I insert into the antrum a drainage tube, and pack loosely around it dry iodoform gauze, but not the external wound, merely keeping their edges separated by a strip of gauze. A tampon is placed in the meatus and the whole well covered with sterilized gauze and cotton. With a favorable course of healing it is sufficient to change the bandage every five or six days. If the temperature does not exceed 101 degrees at any time during the first five or six days, or if elevated temperature is not persistent, there will be no necessity of changing the dressing. When the dressing is changed for the first time the wound and canal should be irrigated with a sublimate solution (1 in 8000 or 10,000), and the wound cavity examined carefully for remaining granulations and roughness which, if found, must be scraped away.

If there is a return of pain after the operation, increased temperature and much septic discharge, which would be indicated by a rapid soaking of the bandages and fetid odor, a daily change of dressing is indicated. So long as the secretion is ill-smelling I use sublimate solution in the strength indicated above. After the bad odor disappears I use a 1 per cent. acid boracic solution. This must be continued until suppuration

ceases. The supposition of Küster and Bergman, that the syringing out of the operation cavity should be avoided, has not been sustained by the profession. So long as there is suppuration in the tympanic cavity the communication between it and the wound must be kept open for free drainage, and only when there is a certainty that suppuration has ceased may the wound be allowed to heal. Occasionally there remains, after the most careful treatment, a sinus in the mastoid process connected with an abscess cavity which requires a second operation. The duration of after-treatment varies from three or four weeks to one or two years before suppuration ceases, and sometimes can not be controlled no matter what is done.

It is wonderful what a beneficial effect the operation often has upon the general system, which may be readily understood when we realize that the blood is kept constantly in a more or less septic condition.

Since 1891 the mastoid operation described above was the typic one, but the collective experience in aural surgery for the last few years has shown that it proves inefficient in many cases, and so search for a more effectual process has developed several methods. In 1891 Stacke of Erfurt, Germany, made known a new operation in chronic cases, based upon the surgical principles involved in the treatment of suppurations within rigid walled cavities; namely, upon the complete and free laying open of the cavity, so that it can be curetted, tamponed and treated surgically, and the operator not compelled to satisfy himself with a more or less imperfect irrigation. The method of Stacke is practically as follows: The cutaneous incision is made a little differently than has been described, the upper part being kept closer to the auricle and carried well around to the front. The lower end must also curve more forward and extend to the tip of the process, the cut circumscribing the auricle. The bone being bared, the membranous meatus is separated from the posterior and superior walls, and its attachment internally being cut, is in its entirety shelled out of the osseous canal. With a small gouge or Dench's cutting forceps the most medial portion of the superior wall of the osseous meatus (lower lateral wall of the attic) is cut away and, if present, the malleus and incus removed. The superior wall is to be chiseled away near the drum insertion till a bent sound touching the tegmen tympani meets with no resistance on being drawn outward. The probe, as a guide, is then turned toward the antrum, and the posterior wall of the meatus chiseled away till that cavity is freely opened up. In this way Stacke converts attic, tympanum, antrum and meatus into one large cavity. After cleansing, the auricle is replaced, sutured, the membrane of osseous canal split and pressed as far back into the enlarged cavity as possible by the iodoform gauze. All subsequent treatment was done through meatus.

This operation proving extremely difficult and unsatisfactory, other methods were suggested, and now what may be known as the Schwartze-Bergman-Stacke operation has been quite generally adopted, and my experience has taught me as being the ideal one in all chronic conditions, which have resisted cure after the ossiculae have been removed. I now rarely perform any other, and am exceedingly happy with the results obtained. It is a much quicker, easier and safer way than the Stacke, and is done as follows: The incision over mastoid and entrance to antrum is made as in the original mastoid operation. The membranous meatus is dislodged as in the Stacke and held

well forward by a retractor. Operative field now shows the posterior-superior osseous canal, the antrum and a bridge of bone separating them. This bridge is now removed by rongeur forceps and chisel, the section being triangular in shape, the apex at the neck of the antrum. Thus the antrum, tympanum and meatus will be converted into one large cavity. Care must be taken at this point not to wound the facial and semicircular canals which lie directly across from this point. As a protection, if a sound is passed through the antrum into the middle ear or, if not possible in that direction, from the middle ear as far as possible into the attic, and confine our operating down to that, we will be within safe grounds. A wound to the external semicircular canal is more unlikely to occur than one of the facial nerve.

As much of the bone should be removed as is compatible with safety, so as to make the antrum and attic as accessible as possible from the external canal (See Allen, p. 103). In this operation I find the dental engine a most useful adjunct. The posterior membranous canal is now split outwardly to the concha as in the Stacke operation, and pressed back as far as possible into the enlarged cavity and held in place by tamponing.

According to Stacke, the tamponing of the membranous meatus into the artificial opening has a double advantage: 1, it secures the formation of a persistent skin-covered communication between the antrum and meatus; 2, it is a skin transplantation, from which the formation of epidermis over the entire cavity can take place. The better way, I believe, is to suture the wound over the mastoid and get primary union if possible, and treat entirely through the meatus. If all goes well the dressings are to remain five or six days, after which daily tamponing must be most carefully followed out.

The granulations must be kept down and the cavity kept as freely accessible and of the same size as just after the operation. Even when the utmost care is taken, minute necrotic pieces of bone become surrounded by granulations, small fistulous canals are formed leading to these dead pieces, around which the suppuration continues even after it has entirely ceased elsewhere.

The duration of the after-treatment varies in these cases also, but is on an average several months shorter than by the old method, and the cure is much more permanent. The indications for this operation are about the same as for the ordinary mastoid.

215 Jefferson Avenue.

PYORRHEA ALVEOLARIS IN MERCURIAL AND LEAD POISONING AND SCURVY.

PAPER NO. 44

Read in the Section on Stomatology at the Forty eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY EUGENE S. TALBOT, M.D., D.D.S.

FELLOW OF THE CHICAGO ACADEMY OF MEDICINE,
CHICAGO, ILL.

In this paper I discuss the pathology of the periodontal membrane as observed in constitutional diseases such as mercurial and lead poisoning and scurvy. In former papers I advocated the theory that pyorrhea resulted from simple inflammation of the gums

¹ Paper No. 1, Dental Cosmos, 1886, p. 689; paper No. 2, *ibid.*, 1896, p. 310; International Dental Journal, January, 1894; paper No. 3, Dental Cosmos, 1896; Journal of the American Medical Association, 1896.

which afterward became chronic, involving the peridental membrane; that it was due to a local factor which would produce this inflammation; that the inflamed membranes became infected with pus germs and as a result liquefaction and degeneration of tissue are produced with or without calcic deposits.

The present contribution is intended to show that the genesis and progress of the pathologic state of the membrane due to constitutional causes is precisely the same. The following cases are of interest from this standpoint:

FIG. 1.—Mercurial poisoning lower left second molar peridental membrane; atheromatous degeneration.

FIG. 2.—Mercurial poisoning, lower left second molar peridental membrane; atheromatous degeneration.

Mr. A., 48 years of age, merchant, was suffering from dyspepsia; was poorly nourished and very weak. His physician placed him upon tonics and calomel. In less than two weeks he came to me with the mucous membrane and gums very much inflamed. The saliva flowed in large quantities; the teeth were loose; the gums swollen; pus oozed from the sockets; the breath had a strong metallic odor. I placed him on six pints of spring water a day and saturated the

gums every alternate day with iodine. I requested his physician to stop the mercurial. In a few days I had reduced the soreness and swelling so that I could remove the deposits from the teeth. The right inferior second molar was so loose that I removed it. He was discharged May 22, cured.

On removal the tooth was placed in 50 per cent. alcohol for twenty-four hours, then absolute alcohol for twenty-four hours. The membrane had receded about two-thirds the length of the root and these microscopic specimens were cut from the lower third

FIG. 3.—Lead poisoning, upper left second bicuspid peridental membrane; atheromatous degeneration.

FIG. 4.—Lead poisoning, upper left second bicuspid peridental membrane; atheromatous degeneration.

of the root. Fig. 1 shows a small fragment of the inflamed peridental membrane; Fig. 2 the round cells of inflammation; the atheromatous degeneration and liquefaction of tissue.

Lead poisoning.—Mr. B., 35 years of age, painter by trade. He was under medical treatment for diabetes. The gums were badly swollen; there was excessive flow of saliva; the teeth were loose; pus flowed from the gums. I put him on two quarts

ozonate spring water per day and saturated the gums as before with tincture of iodin.

Three loose teeth were removed and placed in alcohol for preparation for microscopic examination. These illustrations were taken from the upper third of the left superior second bicuspid and are not unlike Figs. 1 and 2. Fig. 3 shows round cells of inflammation. Fig. 4 is the best specimen of degeneration of

observed the breaking down of tissue. In the center is seen two areas of softened tissue more advanced in degeneration.

The following scorbutic case was referred to me by Dr. George W. Johnson:

The patient, a 25-year-old American, was admitted to the Cook County Hospital for the Insane, Dec. 2, 1892, suffering with melancholia attended by delusions of persecution and suicidal tendencies marked by refusal of food. June 1, 1896, he again began to refuse food but took liquid diet on persuasion. June 29 the patient was transferred to the hospital because of his emaciation. Scorbutic symptoms were discovered. July 18, 1896, the constitutional and local symptoms of scurvy were well marked. The teeth were covered with sordes and loosened. Under anti-scorbutic treatment these symptoms had fully disappeared by Aug. 13, 1896.

Through the kindness of Dr. Johnson I was allowed to see this patient. I found none of the teeth very loose, showing that the disease was superficial. I removed two teeth that were decayed and were loosest. These were prepared as before. Fig. 5 shows the gums and peridental membrane in an active state of inflammation. Fig. 6, the root of the right superior second bicuspid with peridental membrane attached, shows active inflammation and an area of tissue degeneration.

It will be seen, therefore, that in all three cases the same pathologic changes occur in the gums and peridental membrane, whether the original source of gum inflammation be local or constitutional.

The fact that it can be treated successfully locally and that the calcic deposit is never observed in the substance of the peridental membrane, but invariably outside, beyond the pus line, leads me to believe that it is not, *per se*, a constitutional disease, although the local inflammation may be due to constitutional causes; also that there is no such thing as serunal deposits as suggested by Ingersoll, but that the deposits result from pathologic and chemic changes which take place in the tissues themselves, and are a consequence and not the cause. If the technique laid down in former papers be carried out, operators will be successful in treatment.

A CASE OF PROGRESSIVE DISEASE OF THE BONES OF THE FOOT, ANKLE AND LEG.

AMPUTATION AT MIDDLE THIRD OF LIMB WITH THE LOCAL
ANESTHETIC EFFECT OF EUCAIN HYDROCHLORID.

BY DWIGHT S. MOORE, M.D.

JAMESTOWN, N. D.

The patient, E. C., age 71, is of American parentage; his mother, a healthy woman, lived to the age of 70 years. His father when about 30 years of age, had an attack of paralysis which rendered him a cripple. He died at about the age of 35. The son, an active young man, very fond of out-door life, was a servant to an army officer in the Mexican War, accompanying his employer afterward to Texas and Utah and sharing all the privations and dangers of the army.

He had attacks of malarial fever in western Texas. He also had an attack of rheumatism, which was but the precursor of others more severe. During these years he drank considerably at times. He denies ever having had any specific trouble. About fifteen years

FIG. 5.—Scurvy, upper left lateral incisor, high magnifying power, inflammation of the gum and peridental membrane.

FIG. 6.—Scurvy, upper right second bicuspid, high magnifying power; atheromatous degeneration.

the peridental membrane I have ever seen. The different stages of degeneration are well shown. In the corner is seen the root of the tooth, dentine and cementum. The whole surface of the peridental membrane is in a high state of inflammation. Just at the border of the root may be seen an area of membrane softening, and just beyond and joining is

ago he came to North Dakota where he has had many attacks of articular rheumatism, resulting finally in great deformity and helplessness. Some years ago he lost an eye from traumatism. He describes himself as always having been "restless and nervous." He had been spare but strong, active and enduring, till the progress of his arthritic enemy compelled him to more sedentary habits of life. A sister, 68 years of age, and two brothers some years younger, are still living and in good health. There is no history of any tubercular affection in the immediate family of the patient.

About nine years ago the deformity and pain produced by chronic rheumatoid arthritis began to necessitate the use of the cane or crutch. In about two years more two crutches were needed and for over a year past he has been almost helpless, and a part of the time entirely so. The joints affected, by deformity were more especially those of the hands, fingers and knees. The shoulders and hips were not affected, with the exception of great limitation of motion and pain when in action. His fingers deviated from the line of the metacarpal bones, being drawn toward the ulnar side. The joints at the base of all the fingers were greatly enlarged. The joints between the metacarpal bones and the phalanges were flexed. The first phalangeal joints were extended, while the second joints were in a state of slight flexion. The muscles all over the body were wasted and more especially those connected with the joints. This condition is found today, the only difference being that the deformity and helplessness have been accentuated by the lapse of time.

During the winter of 1896-7 a slight redness of the skin appeared between the fourth and fifth toes of the right foot. He says it looked as if it had been scalded. It was sore to the touch and he felt a dull pain occasionally which seemed to be deeply seated. The redness and swelling extended very gradually to the other toes and adjacent portions of the foot, especially affecting the outer border. There was very little external evidence, even at a later date, to show the extensive destruction of bone tissue which was afterward found. Small portions of skin upon three of the toes became gangrenous and bony detritus issued from beneath them along with other products of suppuration. A dull pain of a burning character was felt by the patient almost constantly and referred by him principally to the ulcers upon the toes. The foot became generally of a bluish color and an exploratory incision, followed by the passage of a probe, proved that in spite of the limited local manifestations of the disease a very general death of the bones of the entire foot had taken place. The nutrition of the skin for three inches above the malleoli was impaired. The skin here seemed thin, of a bluish tinge in spots, while pigmentary deposits of a yellowish and brownish color alternated with the bluish discoloration. At the time of this examination it was decided in view of the general symptoms present that speedy removal of the limb would be necessary to save the patient's life.

For some three weeks preceding the time of examination the patient's general condition had been growing more and more serious. The progress of the bony necrosis of the foot, ankle and lower part of both bones of the leg had continued for some time without producing any apparent general symptoms, much external evidence of the extent of bony tissue involved, or much destruction of the soft parts lying next to the diseased bone. At this time the temperature was found run-

ning from 101 to 103 in the evening; the force of the pulse was diminished, though the frequency was not increased as much as is usual with such a temperature. It was soft and compressible. There was almost complete loss of appetite and an obstinate diarrhea persisted in spite of the small quantity of carefully selected food taken. The pain had increased until it had grown almost unbearable, not from extreme acuteness, but from its constant presence and depressing character.

Thus from April to September 1 very little disturbance seems to have existed in a general way from the local disease, but from September 1 till the 16th, when amputation was performed, the general condition of the patient grew rapidly worse. The condition of the joints, muscles and tendons were as previously described. From long inaction and exhaustion from pain, fever, and the probable toxic influence of absorption, the patient was very weak and had great apprehensions regarding the taking of a general anesthetic and the final outcome of the operation, which he was inclined to believe would be fatal. In selecting the anesthetic to be used an examination of the heart was made, with the result of finding that there existed a condition of both chronic pericarditis and endocarditis with a chronic bronchitis. There was a weak and irregular impulse of the heart and considerable precordial anxiety, and occasional pain was complained of by the patient. On account of these intra-thoracic conditions and the great repugnance of the patient to the use of a general anesthetic, and his apprehension that it might cause his death, it was determined to operate under the local effects of eucain.

On the morning of Sept. 16, 1897, the patient, having slept poorly during the night from pain and apprehension, was found to have a temperature of 101 F., pulse 70 and respiration 27. He ate a light breakfast about 7 o'clock and was conveyed to the operating room at about 10 A.M. The ordinary precautions for rendering the skin of the limb aseptic and for performing the operation without danger of infection were carefully attended to. The patient reclined with the head comfortably supported by pillows upon the operating table. A tablespoonful of whisky was administered for its psychical effect, and the limb wound with an Esmarch's bandage, commencing well above the discolored skin on the lower part of the leg. The bandage being unwound was secured by a tourniquet above the knee. The site of the operation was selected nine and three-fourths inches below the lower border of the patella, so that the skin included in the flaps might be entirely normal as regards its appearance. At a point of the limb where it was desirable to have the bone sawn, a hypodermic injection of 5 m. of a saturated solution of eucain hydrochlorid, freshly prepared with sterilized water was made. The limb was girded by a series of these injections about two inches apart. By the time these were made the superficial tissues were sufficiently anesthetized to permit of two or three injections being made into the deeper tissues of the calf, with no perceptible annoyance to the patient. In five minutes anesthesia seemed complete and the flaps were marked out and the operation proceeded with as usual.

An anterior cutaneous and large posterior flap was formed at about the junction of the lower and middle third. The shape of the wasted limb, and the absence of any necessity for the stump being afterward subjected to even the ordinary traction or pressure, mak-

ing it seem preferable to other forms of operation usual in ordinary cases.

Twice during the formation of the posterior flap, the patient complained of a smarting sensation following the use of the knife. The first time an injection of sterilized water removed the ground for complaint. The second time a little severer twinge from incision of that part of the flap lying next to the bone, showed that anesthesia of that portion was not yet complete. A free application was then made with sterilized, borated absorbent cotton wet in the solution of eucain, and in two minutes the operation was resumed on that part of the flap. No further discomfort was experienced by the patient at any time during the operation. The fibula was sawn shorter than the tibia and the sharp crest of the latter again sawn off, and plenty of time was taken to properly trim the large posterior flap. There was considerable oozing from the surfaces of the flaps after loosening the tourniquet, and it was a long operation on this account. Yet, forty-five minutes after the first incision was made, a test showed complete anesthesia of the skin covering the end of the stump. Soon after the operation was begun the patient's pulse rose to 90, which I should attribute to the effect of the whisky and the excitement of the occasion, rather than the eucain. The respirations were not noticeably quickened, and the pulse soon fell again to its usual rate as the operation proceeded.

The stump being properly dressed the patient was carried from the operating room to his ward and placed in bed. He suffered from no depression in pulse or respiration, had no nausea or headache, and in an hour after the operation he was sitting up in bed eating a heartier meal than for some time past. There was no evening exacerbation of temperature, and after twenty-four hours the temperature was normal and it has since remained so. The pain in the stump after operation was at a minimum and perfect union was obtained. The stitches were removed and the stump examined at the expiration of nine days, and it was found entirely healed. During this time there was a remarkable improvement in the strength, appetite and general appearance of the patient, which has continued till the present time. The previous disease causing his confinement to bed or chair persists to nearly as great an extent as before, suffering exacerbations from nearly every change in temperature and humidity.

The metatarsal bones of the diseased foot to a great extent were enlarged, softened and of a dark red appearance internally. The whole of the tarsus was similarly affected, the cells of the bones being filled with a reddish, serous, glairy fluid and with soft granulations of feeble vitality. The bones were everywhere so softened that after a thin layer or sequestrum was removed an ordinary probe penetrated the carious tissue with ease. The lower part of both tibia and fibula were in much the same condition. The intervening joints appeared intact, though the muscular planes and areolar connective tissue had diffused through them everywhere, sero-purulent and mucopurulent liquid. This purulent infiltration of the soft tissues extended to within an inch of the lower border of the posterior flap.

This operation shows conclusively that in those cases where previously existing pathologic conditions, or other causes render the administration of a general anesthetic dangerous or inadvisable, the use of eucain will enable us to perform a painless operation, free from all the dangers and annoyances attending the

use of chloroform or ether during their administration, the performance of the operation, or the emergence from the anesthetic condition.

REVIEW OF THE OPERATIVE TECHNIQUE ADOPTED IN DETERMINING THE LO- CATION OF INTESTINAL OBSTRUC- TION, WITH THE SUGGESTION OF A SIMPLE AND SAFE METHOD.

BY ROBERT J. REED, M.D.

WHEELING, W. VA.

In the surgery of intestinal obstruction, the steps of chief importance in the operative technique are the removal of the cause of the obstruction when located, and the repair, if necessary, of the wounded bowel. Final success, however, depends upon the general condition in which the patient is left at the end of the operation, as much as upon the condition of the liberated intestine. All the preliminary steps, therefore, should be so ordered as to avoid unnecessary sacrifice of time or the infliction of injury by mischievous bowel manipulation.

In addition to the remote danger of intestinal paresis and peritonitis, there is another more imminent. Shock is the prominent element of danger in the operative interference for relief of this condition. It is already present, usually in a marked degree, as a result of the injury the intestine has sustained, as well as from the depressing effects of the vomiting and pain to which the patient has been subjected. Whatever deepens the shock, be it a prolonged operation or extensive handling of the intestines, diminishes the probability of favorable reaction and the patient's recovery. Authorities make the statement, and truthfully, that the nature and location of the obstruction can not be known until an abdominal section has been made, but they permit the inference to be drawn that the situation of the stricture is then readily ascertained. One, under this impression, undertaking such an operation with limited experience, may meet with profound surprise. Locating the point of obstruction with the hand among the intestines is in a large proportion of cases a difficult and perplexing procedure.

The first step in the operation for the relief of intestinal obstruction involves an important question, the situation of the incision into the abdominal cavity. Should an induration or tumefaction be felt, the temptation is great and the decision apparently a rational one to make the section directly over that point. But in a majority of cases it will prove a mistake and result in disappointment and confusion. The local swelling which presents may be a loop of distended intestine, a section of rigid muscle or a fecal collection, and be situated at a distance from the seat of obstruction. The best selection is the median line below the umbilicus, save in very exceptional instances. Its advantages are many over any other position. The incision has less depth than in any other location, and therefore may be shorter. It is made with greater speed and less hemorrhage. Being in a central position, every portion of the cavity can be investigated with equal ease and dispatch. In case of gangrenous bowel and fecal escape the danger of infection is less than if planes of connective tissue are laid open, as is done when departing from the linea alba.

The one disadvantage of the median incision is made manifest should the obstruction be found in the large intestine. Because of its short mesenteric attachment, it may be impossible to bring the strictured portion into the wound, and consequently a second section to the side will be necessary. This consumes time and adds somewhat to the shock, but the chief objection is, that with the intestines tensely distended, as they frequently are in obstruction, the difficulty of preventing their protrusion with two openings through the abdominal wall is greatly increased. Consequently if there be exceptions to the rule of the median line incision, it should be in those cases in which the history is convincing and the symptoms presented corroborative of the diagnosis of involvement of the colon. The evidences of obstruction in the lower bowel are usually clear and easily differentiated from those presented in occlusion of the small intestine. If in addition to the history and symptoms, a tumor can be felt in the line of the ascending or descending colon, an incision in this location would be expedient and justifiable. In case a second section of the abdominal wall is for any reason necessary, it is a judicious procedure to carefully close by sutures the primary incision as soon as the stricture is located, not waiting, as is usual, to make it a final step in the operation. By this precaution one way for the escape of distended loops of intestine is closed and their exposure and handling avoided.

After the cavity has been entered the difficult work of the surgeon begins. It consists in promptly discovering the position of the obstruction without resorting to means which will increase the dangers from shock and peritonitis. If its exact location can not readily be ascertained, a measure frequently resorted to as a way out of the dilemma is evisceration. Only a limited experience is necessary to bring the conviction that this procedure should be strongly condemned. The intestines are withdrawn with ease, but returned with difficulty. They are greatly distended, even the collapsed portions will probably become so, the moment the stricture is relieved, or if above it, as soon as they are withdrawn. If a great extent of bowel has in this condition protruded, it is replaced through a section of usual length with great difficulty, requiring not only the hands of the operator, but those of an assistant as well, both laboring from every direction and exerting actual force in their efforts. Injury to the intestine must necessarily be inflicted. If careful handling of the bowels results in a degree of shock, as is frequently observed in abdominal surgery, how much greater must be the danger when the manipulations required involve positive roughness. In addition, the bowels are exposed to a variable temperature. The attempt is made to give them warmth and protection with hot towels; but these are always too hot or too cold. It is impossible to obtain through them a proper and uniform heat, but with this object in view there must be a constant changing and replacing of the cool with warmer towels. This variable temperature, together with the mechanical irritation from the towels, unquestionably encourages the development of peritonitis. Undoubtedly it should be the chief care of one assistant to prevent the protrusion of the viscera.

Securing the collapsed bowel and "following it up to the stricture" is considered an invaluable aid. This was announced as a new idea ten or more years ago by Mr. Hulke of England. It has been exten-

sively adopted, and I have been unable to find any criticism of it. The suggestion is founded upon the theory that collapsed bowel is found only below the obstruction. This, however, is a fallacy. It is present not infrequently above, sufficiently often to make it an unsatisfactory guide. If this method is selected it may result in the handling of the entire small intestine as far as the duodenum before the mistake is discovered that the investigation is being made in the wrong direction. In a case which came under my observation the obstruction was in the sigmoid flexure and yet the greater portion of the small bowel was collapsed.

A rational solution of the problem presented in such a condition would seem to be that the bowel above the obstruction being greatly distended, the muscular coat becomes paralyzed for a considerable distance, until a point is reached where the muscular tone of the intestinal wall is unimpaired and consequently less distended. This disparity in the lumen and tone of the intestine encourages the formation of an angle, and as the meteorism increases and the abdominal tension becomes great, the angle is made more acute, and the healthy segment is flattened out by the pressure from the distended loops sufficient to occlude it. On the other hand, the vomiting becomes severe and persistent, peristalsis is reversed, the intestine is gradually emptied and consequently collapses. This condition probably occurs only in the small bowel, the short mesenteric attachment of the colon preventing its developing such a complication. This explanation of the formation of the kink in the intestine and its collapse may be fallacious, but the fact remains that collapsed bowel is found at times above the obstructed point as well as below, and therefore, is not a reliable guide, as it is impossible to know in which direction to follow it. And this statement holds true, although less mischief will be done when tracing collapsed bowel below the stricture. One is unable to decide until a large extent of intestine has been handled, whether the search is being made toward the point of obstruction or away from it.

In the effort to locate the stricture the sense of touch must be largely utilized. It is also important that a definite plan of investigation be fixed in the mind of the operator. An order of procedure, which will prove expeditious is, with the entire hand in the cavity, to first explore the left inguinal region, excluding the possibility of obstruction at the hernial orifices upon that side. With the hand in this location it is an easy matter to examine into the condition of the sigmoid flexure. If it is found in a state of distension the inference may at once be drawn that the obstruction is below. If collapsed, it is above. The next step should be the exploration of the right inguinal region, the hernial orifices upon that side, and the cecum. Should it be found distended, the conclusion must be that the obstruction is the colon. With this much known it is not a difficult matter to locate it definitely by either following down the distended colon or returning to the left side and tracing up the collapsed portion. If the cecum is collapsed the difficulty is above in the lesser bowel. It is at this time that a selection must be made of the method by which some eighteen feet of intestine are to be examined.

A less difficult and much safer method than those which have been named, evisceration or following collapsed bowel, is one dependent upon what may properly be termed the *color guide*. I am not aware that

attention has been called to it, but in my experience it has proven a helpful and practicable idea.

At the seat of strangulation, circulatory changes begin at once, which will soon be manifested in the serous coat, to the eye; a congestion which deepens and extends further along the distended bowel the longer its exciting cause continues. Should it be some hours, not inches, but feet of the bowel will exhibit a highly colored, injected appearance, which fades from a scarlet at the point of stricture into a pink, and finally is lost in the normal white or gray color. The suggestion is, cautiously bring one loop after another of distended intestine into view at the bottom of the abdominal incision, being directed by the sense of touch to those loops tensely distended, as they are nearest the stricture. By carefully noting their appearance a clew will shortly be found in a loop of congested bowel, and by tracing along in the direction in which the color is deepening the obstruction will be located.

73 Twelfth Street.

HARE LIP, A CASE IN PRACTICE.

Presented to the Section on Stomatology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY GEO. T. CARPENTER, M.D., D.D.S.

PROFESSOR OF ORAL SURGERY, COLUMBIAN DENTAL COLLEGE; INSTRUCTOR IN NOSE AND THROAT DEPARTMENT COLLEGE OF PHYSICIANS AND SURGEONS.
CHICAGO, ILL.

The patient, a lady 22 years old, had suffered from birth with double hare lip, also cleft of both hard and soft palate, which was very large, but nature had largely overcome this latter defect by hypertrophy of

the country. Owing to her mother's opposition to surgery the lip was not operated on. The lady was of a healthy and well-developed family. She came to Chicago and I was consulted and an appointment made for July 28, 1896, at which time Figs. 1 and 2 were taken, after which I made a careful examination and found that five anterior teeth were very irregular

Figure 2.

Figure 1.

Figure 3.

the inferior turbinated bodies, and, in consequence, the voice, though not good, was much better than many with a very slight opening in the hard palate or bifurcation of the velum. But the deformity of the lip did not improve. The patient was well developed, strong and healthy. She had always lived in

and badly decayed, the two centrals being movable on account of the loose intermaxillary bones; the cuspids were irregular, but sound. I also took a sectional impression of the upper part of mouth. I then used local applications of 10 per cent. aqueous solution of cocain and removed seven teeth, one of which

was a supernumerary. As soon as the gums were healed a rubber plate with six anterior teeth and soft rubber velum was inserted, and on September 15 we operated on the lip. The operation was performed under ether. We first removed the mucous membrane, with considerable tissue, from the central teat-like projection. We then passed a lancet through the lip of each side, and cut upward and toward the median line to the extreme upper angle of the cleft. Adhesions of the lip and gum were also freely separated by the use of the knife; then turning the flaps down (the assistant pressing the cheeks well forward), the surfaces of the flaps were brought together. Three deep catgut stitches were taken in the under side of the lip. The margin of the wound was then neatly placed in position and secured by a few fine stitches. Cohesive strips of English moleskin were placed on each cheek, which were allowed to extend to the corners of the mouth and turned under, so as to leave free the anterior ends, which had holes punched for lacing. The surgical dressing was powdered iodoform, covered with 10 per cent. iodoform gauze. The cohesive strips were then laced tightly, so as to bring the cheeks well forward and relieve all tension on the stitches. Dobell's solution was used as a mouth-wash. The lacing was removed and the wound examined each day for a week. The fine stitches were removed the third and deep stitches the sixth day. We had union by first intention. The patient was dismissed October 12, upon which date the photograph Fig. 3 was taken.

TREATMENT OF CARBUNCLE.

BY JOHN PHILLIPS, M.D.

STEVENS POINT, WIS.

The JOURNAL of Dec. 12, 1896, p. 1226, contained an article by W. E. Shaw, M.D., of Cincinnati, on the "Conservative Treatment for Carbuncle." My own observations have been so entirely different from the teachings of this article that I am constrained to make a most decided protest against this plan of no treatment, or next to none, of this most formidable disease.

It was the fortune of the writer, in the autumn of 1865, to suffer from a large and most painful carbuncle, located centrally on the back, overlapping both scapulae, which was aggravated by attending to professional duties for a week after the disease had made its appearance, not only at home but during the same time making three trips in a buggy a distance of twenty-two miles, returning home in the evening much chilled. By this time I was obliged to go to bed and remain there for the next four weeks, bearing with reasonable fortitude the pain which one writer speaks of as horrible. Gross says: "The pain is throbbing and exceedingly violent, the part feeling as if in contact with melted lead." One who had had personal experience, compared the pain to that of a "large claw, with a hundred talons, grasped into the swollen, inflamed and now exquisitely painful parts, and slowly but constantly tightening its grasp, for days, for weeks, till the last vestige of life is tortured out of the diseased structures." These descriptions of the pain, which may at times be modified in persons and in location, are as nearly correct as any that can be given. Finally recovering, it was with a fixed determination that no patient of mine should suffer as I had with a carbuncle. I

realized that it was a formidable disease and that little benefit resulted from the measures then being used and believed one would be justified in using more heroic measures in treatment.

In March, 1867, I attended Judge B., 65 years of age, of powerful frame and iron constitution, but considerably broken by hardships and exposures. I found him suffering intensely with a carbuncle of the upper lip. His lip, face, nose and forehead were much swollen. One eye was entirely closed, the other nearly so. A full dose of opium was given at once and pieces of caustic potash were put in two of the three openings in the lip. The potash was pressed well below the surface and the bloody exudation was from time to time carefully wiped away, much care being taken to protect the external surface. The potash was allowed to remain for about twenty minutes, then the wound was well washed out with weakened vinegar, dressed with a warm poultice well wet with tincture of opium, another anodyne was given and the patient dismissed for the night. The next morning all was changed. Nearly all swelling of the lip as well as of the other parts was gone. In reply to my inquiry as to his condition, he said, seizing his lip, "It got well last night; it is a little sore when I pinch it, but it has not given me a bit of pain since an hour after you left me." It did not give him further pain. With dressings of mild cerate it soon healed, leaving but a slight cicatrix.

About two years later I attended the same patient and again found him suffering with a carbuncle, a little above and back of the right hip, but as yet showing no openings. His health was more broken than formerly, having suffered many weeks with sciatica. Dreading the knife, the potash was applied direct to the carbuncle. A plaster of cerate was liberally covered with the caustic and applied, the carbuncle having been first covered with soft leather (buckskin) through which an opening had been made three-fourths of an inch in diameter. The caustic was allowed to remain about forty-five minutes, to make sure of its reaching the deeper diseased structures. The local after-treatment was about the same as at the former time and the results similar. There was no pain except for a short time after the burning. A change, in a few hours, from torture to a quiet and restful condition.

A few months later I attended Barney D., 45 years of age, much broken in health by exposure and stimulants, who was suffering from a large carbuncle on the back of his neck. The parts were greatly swollen, indurated and exceedingly painful. Anodynes, stimulants and tonics were administered and the caustic¹ liberally applied, pressing it deep into three of the four openings already existing. This was done notwithstanding the seeming certainty of approaching dissolution. The local after-treatment was similar to that in former cases and the result quite as favorable. The use of the potash was followed by a restful sleep and the same calm hopeful condition.

The next case was that of Mr. C., who was suffering with a large carbuncle just above and a little to the left, but encroaching on the umbilicus. The swelling was large, indurated and exceedingly painful. First making a free incision, the caustic was pressed

¹ I usually put a piece of stick caustic about one-sixth to one-fourth of an inch in length in each opening. In the first case only half this quantity was used.

well into three places, one-half inch apart, and allowed to remain about twenty-five minutes, in the meantime carefully wiping away the bloody exudation. The wound was then washed out with weakened vinegar, as in other cases. Poultices were next applied and changed once an hour for a few hours, while the discharge was profuse. Then the cerate dressing was used and the wound soon healed. In two hours the condition of this man was changed from that of torture with great depression to one of calm quiet.

It is thirty years since commencing the treatment of carbuncle by the caustic method and while the number of cases has only been about twenty, and half that number brought to my knowledge by physicians to whom I had recommended this treatment, the results have been so uniformly satisfactory, that I have not cared to try injections or excision. It must, however, be remembered that the remedy is a heroic one with which harm may be done if not used with care.

Dr. Marks of Milwaukee has recently treated a carbuncle successfully by the caustic method. He, however, used the nitrate of silver instead of the potash, and in this case with equal benefit. Now if the caustic silver will uniformly or generally destroy the carbuncle it will be more desirable than the stronger caustic, as the destruction of the soft parts will be much less and little or no care will be required to prevent the destruction of the integument. My own impression had been that the milder caustic would limit its own action and fail to permeate and destroy all of the diseased structure. But the success in this case will warrant the further trial of the silver.

At the close of a heated term in August, 1896, a cold blast from the north came in the night, and awakening in the morning I found myself shivering with cold. Within a day or two a small tubercle was discovered on the back of the neck and I had not long to wait to know that it was a carbuncle. The sulphid of calcium was taken (ten to twelve 0.03 gram pills daily) till the system was saturated, seemingly with no effect on the disease, as within a very few days the swelling extended quite across the neck, a little onto the back, and well up onto the scalp. I now had Dr. R. use the knife and potash on the carbuncle. Three days later two incisions were made, followed with the potash; two days later two incisions and more potash; two days later another incision and potash; two days after this two incisions and potash. The last time positive orders were given to continue the use of the potash till the last vestige of the diseased structure had been destroyed. The night previous had been passed as in a nightmare. I was enabled to get through the night only by the vigorous use of artificial heat, stimulants, hot broths, trinitrin, strychnin and quinin. This last burning was followed by a restful sleep.² As a result of the many burnings an open sore was left, five by two and one-half inches in extent and deep enough to convince the surgeon who follows the excision method of treatment that in this case a remedy even more heroic than the knife had been used. Within three weeks my weight had been reduced from 162 to 129 pounds and my strength so lessened that I could go from one bed to another only by the aid of an assistant. A good recovery was made,

though the healing of the wound was protracted till the beginning of December.

It may be asked, why this tardiness of the potash in doing its work? It was used timidly (against the advice of others), too sparingly, too near the surface, destroying the integument but failing to fully reach the deeper diseased structures. Another element, entering into the cause of the obstinacy of the disease, may have been the condition of the urine, which was found, about the time of the last burning, to be loaded with sugar. All cases save one, treated by myself with the potash, and all cases coming to my knowledge, treated by other physicians with this remedy have made good and rapid recoveries. The one exception was the case of a Polish woman, 50 years of age, with bad surroundings.

She was treated in August, 1895, for a large and greatly indurated carbuncle, the induration occupying all of the back of the neck. Following a free incision the potash was liberally applied at three points in the incision, but the benefit proved but temporary, the pain returning in force in the evening, and the woman died the second morning before making my second visit. This case, as well as my own, shows the necessity of an early repetition when the first burning proves insufficient. Chloroform may be used during the cutting and burning, at the same time giving trinitrin, strychnin and codein. Quinin, iron, strychnin, arsenic and sulphid of calcium are some of the drugs that may be given with benefit following the local treatment.

As to the choice between the radical and the conservative methods of treatment of this formidable disease, it would seem there should be no hesitancy. In the use of the potash there is, or may be, considerable destruction of the soft parts, but the disease itself, the horrible pain and the danger to life from septicemia, or from the grip of the disease on all of the life powers, is eradicated. Only an ulcer, tender but painless, is left, which soon heals, giving little trouble after the burning. With the conservative treatment the destruction of the soft parts is nearly, if not quite, as great as when the caustic is used, and the ulcerative process continues for weeks attended with horrible pain. Add to this the very considerable percentage of deaths occurring under the conservative treatment, and I feel assured that the surgeon or the patient who has tried the more radical treatment will consider no other.

TREATMENT OF HEMORRHAGE FROM THE GENITALS IN OBSTETRIC PRACTICE.

Read before the Wayne County Medical Society, at Belleville, Mich.,
Oct. 14, 1897.

BY GUSTAVUS M. BLECH, M.D.

CHICAGO, ILL.

Pathologic hemorrhage means danger to the life of the patient. Hemorrhage in obstetric practice, particularly during and after parturition, occurs with sufficient frequency to warrant the practitioner to be prepared for it whenever called to a case of labor. Hemorrhage even of a threatening character may also occur at any time during pregnancy.

Hemorrhage, like all other emergency cases, calls for prompt action on the part of the physician. There is no time to look up the subject in text books or even to consult a more experienced practitioner, hence everyone is expected to be thoroughly familiar with the pathology and therapy of all emergencies of whatever character. However, in spite of the most rational

²It is noteworthy that after each burning, as the pain caused by the potash subsided, there was a restful period for an hour or two, with a feeling as if about to get well. But in a few hours the pain would be back with the same tightening grasp, but after the second burning not with quite the original force.

aid rendered, life can not always be saved, but if the surgeon does not lose his presence of mind, diagnoses the case properly, has all the necessary apparatus at hand, and above all operates aseptically he can conscientiously say that the patient succumbed in spite of treatment.

Presence of mind will do much. In the first case of postpartum hemorrhage to which I was called I found the attending accoucheur, a young and irregular physician, in a state of mental disturbance. I arrived after the hemorrhage had stopped spontaneously. As I was met by the woman's husband on the street, I had nothing but a hypodermic syringe with me. As soon as I arrived I removed the placenta, lying partially in the vagina, partially in the cervix, and commenced heroic stimulation, auto-transfusion, etc., but in spite of all the woman expired in a few minutes. During that time the "attending" physician was helpless, unable to render me the least assistance. He had in his satchel nothing but a few bottles, a pair of scissors, and an ounce of cotton. Had this woman received prompt and rational aid I am confident she would be alive today. On the other hand, Dr. Steinbrecher related a similar case in which Credé's manipulations failed to cause contractions of the uterus quick enough to stop the hemorrhage. Noticing a large piece of ice in a pitcher of water the doctor pushed the ice into the uterus and the woman owes him her life, and a bill.

I have divided my essay into two parts, viz.: hemorrhages during pregnancy and in those met postpartum.

HEMORRHAGES DURING PREGNANCY.

They may come from either the vulva, vagina or uterus. The vulva may bleed from lacerations or injuries of a traumatic character, the vagina from ulceration or decubitus caused by ill-fitting pessaries, which forms of hemorrhage have nothing to do with pregnancy, hence will not be further considered.

Hemorrhages not infrequently coming from varices, usually in the neighborhood of the labia majora or minora or around the clitoris are very serious indeed. The rupture of a varicose vein may under some circumstances lead to death in a few minutes, but usually in one or two hours. The diagnosis is easy. On careful examination the torn varicose vessel will be found and recognized.

If the hemorrhage does not come from the vulva, the entire vagina and the vaginal portion of the cervix should be examined next, for not infrequently, carcinoma complicated as it is by pregnancy leads to grave hemorrhages. Undoubtedly pregnancy, on account of the general hyperemic condition of the genito-reproductive apparatus, influences the neoplasm, making it hyperemic and softer, thus inducing ulceration and decomposition. In such cases, the diagnosis from a prognostic as well as therapeutic point of view is important, for delay in rendering radical aid may mean a loss to the mother which can not be restored. In progressed cases of carcinoma of the vagina or vaginal portion of the uterus the trained finger and eye of the examiner will prove sufficient to recognize the true character of the growth by touch and macroscopic inspection. In incipient or otherwise doubtful cases the microscope will settle all doubts. In this connection I may also mention myomata as apt to cause hemorrhage in obstetric practice. They are however but rarely met with. Personally I

have no experience with them in that direction, having seen them only in gynecologic practice as an obstacle to conception. Hemorrhages coming from the uterus, even in the first few months of pregnancy are of greater importance. In most instances, they mean abortion or conditions which may require the induction of abortion or artificial labor. The diagnosis of threatening abortion offers hardly any difficulties. The history of the case, perhaps the existence of certain constitutional troubles, previous abortions and the presence of periodical pain, will help us to explain the nature of the hemorrhage. By means of an exploration of the uterus through the cervix (if this be possible) as well as by inspection of the expelled blood clots, ovum and secundines we may determine whether or not abortion has already taken place. This is the most important question to be answered, as without this, scientific treatment can not be instituted.

Of grave importance to the mother as well as to the child are hemorrhages due to either lateral or central, complete or incomplete placenta previa. The situation is still more serious when hemorrhages occur from a separation of the normally situated placenta. It is nearly always fatal to the fetus. The diagnosis of this condition is not always easy, especially when the blood does not escape per vaginam, but collects in the uterine cavity. However, the existing pains without contraction of the uterus, while the latter becomes abnormally large, finally symptoms of collapse as observed in cases of exsanguination, will hardly leave us in doubt as to the nature of the trouble.

These are the most important forms of hemorrhage from the genito-reproductive apparatus occurring during pregnancy.

POSTPARTUM HEMORRHAGE.

I shall never forget my first case of forceps delivery. I administered chloroform, applied forceps and delivered a semi-asphyxiated boy and resuscitated him by artificial respiration. As soon as the first cry was heard, husband and friends came in hastily, but stood quietly with the same sorrowful looks on their countenances. I asked them whether they were not satisfied, and received this answer: "We never congratulate the parturient until the mother cake is removed." I removed the placenta after ten minutes waiting. I have learned a lesson since then and, like the Jews, look upon that "mother cake" with much respect, for if it does not come quick enough and we help it along a little, postpartum hemorrhage and sepsis frequently result. This plainly teaches us to leave the placenta alone. Let the uterus expel it into the vagina, and if you give it time enough, it will do so more or less faithfully in every instance.

Lacerations which occurred during delivery may give rise to considerable hemorrhage. Under this heading we may mention rupture of the uterus, terminating fatally only too often. If these be not the cause of a postpartum hemorrhage then it is due to inefficient contractions of the uterus-atonny. There are many causes for such a condition, but I shall mention only one, an overfilled bladder. In all cases of postpartum hemorrhage due to uterine atony this should be considered and the bladder catheterized.

The most reliable way to make a correct diagnosis of post partum hemorrhage is by means of a physical examination. This is in all instances to be preferred to a diagnosis made by deduction from a number of symptoms, but before making an exploration of vulva.

vagina or uterus, let us remember that while these organs are aseptic in a healthy pregnant woman they are no more so after delivery, but on the contrary in a condition particularly disposed to infection. Therefore, thorough asepsis is *conditio sine qua non* whenever we have to bring finger, hand or instrument in contact with the genitals.

Care should be taken in the attempt to disinfect the genitals. If you throw in solutions of boric acid or, as I have seen a young physician do, a teaspoonful of listerin in several pints of water, you may just as well use plain warm water, it is just as effective. Weak solutions of bichlorid of mercury and carbolic acid will not render the parts aseptic: stronger solutions will cause intoxication by absorption. I rely solely upon hydrozone which is as bland as water, non-toxic and yet kills the ordinary pathogenic micro-organisms in a few seconds by oxidation. In this I am sustained by the leading surgeons in this country. In Europe the value of H_2O_2 has not yet been appreciated as much as here, which is probably due to the fact that every druggist prepares the official solution in his little laboratory room, though in reality it requires unusual skill and extensive machinery to make an efficient solution.

A ruptured varicose vessel is best treated by compression with a piece of plain aseptic gauze. In many instances this procedure, if continued for a while will prove sufficient to arrest the hemorrhage. If it does not then we will have to treat it operatively. Hematomata, if any exist, should be excised, that is, the sac should be opened and emptied. Ordinary suturing of the vessel will not suffice, as every insertion of the needle causes a certain amount of bleeding and therefore deep sutures, inserted vertically to the varix, are required to stop the hemorrhage.

The first step in arresting a hemorrhage from carcinoma is to tampon the vagina, cervix or uterus. With the temporary arrest of the hemorrhage however, our work is not completed. Carcinoma in pregnancy is so rapidly fatal that radical measures have to be taken to save the life of the woman. Where the vagina is but little involved excision or curettage may suffice. In the latter stages of pregnancy, when we have reason to believe that the child is capable of life, artificial labor should be induced before performing hysterectomy. Whether we should operate per vaginam or make laparotomy depends entirely on a variety of circumstances with which every surgeon is familiar and which vary in every case. I have nothing new to suggest in the treatment of threatened or completed abortion, the management of which is clearly outlined in every standard text-book.

In hemorrhages due to placenta previa rest and opiates are to be first tried. But not too much time should be spent with either. If they prove inefficient we must proceed to tampon the vagina, which will promptly arrest the hemorrhage. By this means as well as by the loss of blood artificial labor is frequently induced. With the commencement of labor more placenta is detached and the opened uterine vessels, unable to contract, bleed more profusely. Naturally, with the rupture of the bag of waters and speedy delivery of the fetus all would be well, but unfortunately, this does not always occur. Braxton-Hicks' version in malpositions of the fetus is the remedy *par excellence* but should never be practiced unless there be sufficient dilatation of the os, because otherwise we are apt to lacerate it. The renewed hemor-

rhage which such a laceration causes might prove fatal to the already exhausted woman. To cause sufficient dilatation of the os, I know of no better means than the introduction into the uterus of a previously sterilized colpeurynter after rupturing the bag of waters. When the filled colpeurynter is expelled into the vagina the dilatation obtained is sufficient to permit of the execution of Braxton-Hicks' version safely. As long as the colpeurynter lies in the uterus it acts also indirectly as a hemostatic by pressing the placenta against the uterine wall.

Immediate delivery is the only rational treatment of premature detachment of the normally situated placenta. The uterus only should be dilated by colpeurynter or other mechanical means, hot douches administered to excite pains, then rupture of the bag of waters takes place and either instrumental or spontaneous delivery follows. No time should be lost if we want to save the life of the mother—the life of the child can not be considered. If for any reason delivery can not be accomplished, Cæsarean section may be strongly considered and executed.

Perineal, vaginal or cervical lacerations producing more or less severe hemorrhages, must be immediately repaired by suturing, taking care to coapt the wound surfaces properly.

If pathologic hemorrhage is not due to lacerations then atony of the uterus is the cause. Insufficient contraction of the uterus may be due to over-exertion of the muscle after prolonged and hard labor or unusual pressure, frequently also to a full bladder. We should, therefore first catheterize the bladder and then attempt to cause contractions by systematic friction of the fundus with the full hand. If we succeed in causing contraction and the hemorrhage still exists, Credé's expression of the placenta should be practiced. Failing in this we may inject strychnin, administer a vaginal douche and try friction and expression; again failing in this the placenta should be removed manually, under due antiseptic precautions. The introduction of the hand into the uterus will often excite strong contractions. But in spite of the manual removal of the placenta, contractions may fail to appear, causing dangerous hemorrhage. This also happens after spontaneous expulsion of the placenta. In such cases ergot is indicated; 3.7 or 7.4 c.c. of a reliable fluid extract, preferably of the non-irritant preparation ergotole, should be injected hypodermically, followed by hot intra-uterine irrigation. Failing with these methods, there remains but one thing to be done—tamponing of the uterine cavity with aseptic gauze, which may also be first soaked in a chlorid of iron or, better still, peroxid of hydrogen solution.

Rupture of the uterus means laparotomy or death.

I can not conclude my paper without a few words in regard to the treatment of the acute anemia which obstetric hemorrhages usually cause. We have arrested the hemorrhage but our duty does not cease there, for the acute anemia may prove fatal. Besides the usual stimulants such as strychnin, nitroglycerin, amyl nitrite, camphorated ether, strong coffee, alcohol and milk, heat should be applied all over the body, while the patient lies with the head low and the body and lower extremities high. Auto-transfusion by means of an elastic bandage around legs is to be rejected on account of the possibility of embolism from old varices. Direct transfusion is desirable, though a complicated procedure not easily carried out in every instance. But no woman should be allowed

to die without the intravenous or at least intracellular injection of normal saline solution. The injection in a vein is better but requires skill. Every physician working aseptically can, however, thrust a needle emptied of air into the subclavicular region. A pint can be injected in this way every fifteen minutes and no harm will result. Although the lost red blood corpuscles can not be replaced by the saline solution, the value is apparent in many other directions, and as it is a very simple procedure it should be practiced in every case of hemorrhage, obstetric, surgical or otherwise. The normal salt solution I employ is a sterilized 0.6 per cent. solution of sodium chlorid (c. p.). I keep several pints on hand. When needed the bottle is placed in hot water until the solution reaches a temperature of about 102 degrees.

When injecting in the subclavicular region a tumor is soon formed, which can be caused to be absorbed by gentle massage.

A CLINICAL STUDY IN PELVIC MASSAGE.

BY HOMER C. BLOOM, M.D.

OUT-DOOR SURGEON TO THE GYNECEAN HOSPITAL,
PHILADELPHIA, PA.

The purpose and scope of this paper is not to discuss the merits or demerits of pelvic massage. This is a matter which will necessarily follow the adoption of any new treatment, and especially one that is in any way open to objection. At the very threshold of this subject it is easy to anticipate the objections which are likely to be raised relative to the handling of organs and tissues which are the local seat of sexuality and passion. Yet that liberality which characterizes the true physician and surgeon will always seek to find the level by which any new treatment can be taken.

Therefore, it is not for any one to emphasize or declare the status of a treatment which must be judged entirely upon those results which accrue from its practical application. Accordingly, this paper will not only deal with the positive but with the negative results, the basis of which is the record of some fifty cases covering a period of almost one year.

This particular study of pelvic massage was at the suggestion of Dr. Charles B. Penrose, who proposed a trial of this treatment in the out-door department of the Gynceean Hospital. A graduate nurse was secured who had given her time to the study of this particular massage, under the tutorship of a pupil direct from Brandt of Sweden.

Twenty of these cases were undeveloped infantile conditions of the pelvic organs, especially of the uterus, with those symptoms which characterize more or less such a condition; scanty and painful menses, often irregular and mostly attended by those nervous reflex manifestations which make these cases among the saddest and most unsatisfactory that can be met with.

Case 1.—Miss D., aged 24 years; puberty at 16; menses very scanty, lasting only a few hours, attended with severe central abdominal pain, also intense low down backache. Flushes of heat, headache, more or less mental depression and constant worry; bowels constipated. This embraces the history since puberty with the exception that her menses, which are less frequent, are attended with more pain. Examination revealed a small infantile uterus. It was impossible to palpate the ovaries; otherwise negative.

Pelvic massage was advised and the first treatment given September 19, lasting fifteen minutes. A treatment again on September 22, 24, 26, 28, October 1, 3 and 6, period coming on the next day, October 7, lasting two full days, then stopped. Treatment was resumed October 11, when she again com-

menced to flow and continued for twenty-four hours. She had more flow and much less pain than ever before during any single period. Second period came on November 4, lasting until November 6, and returned November 9, lasting twenty-four hours. She had more flow and it was a better color. Third period December 2, lasting until December 3, returned on December 6, lasting two days, attended with less pain and more flow than at any other past menstruation. Fourth period January 1, lasting for three days with no pain, more flow and lasted longer than any period heretofore. During these months the treatments were continued every third day. An examination in January showed the uterus to be larger in every direction and more fully developed.

These treatments were omitted in January, a request made to the patient to call once a month; this she failed to do and I did not see her until the first of May, when she was again examined and everything found satisfactory. The history since has been normal as to time, lasting three days with no pain worth speaking of.

Case 2.—Mrs. B., aged 35 years; puberty at 15; scanty, painful menstruation; married three years, sterile. Examination showed small undeveloped uterus, ovaries not palpated; pelvic massage advised. First treatment September 22 for fifteen minutes; September 24, 26, 28, 30, October 2, 6 and 9, menses appearing on this day, scanty, less pain and lasting five days. Second menses November 12; had pain and cramps; dark-colored clots and very offensive. Third period December 14, lasting five full days; free flow and no pain or discomfort.

These treatments were continued every third day in this case.

At the expiration of four months an examination showed a marked improvement and a better development of the uterus in every direction. This patient in March was free from all symptoms.

The third case illustrates that principle which has no exception, that certain lines of treatment may cure some cases and not others.

Case 3.—Annie W., aged 18 years; puberty at 17; always had irregular, painful, scanty menstruation. Examination showed infantile condition of the uterus; ovaries not palpable. After seven treatments the menses appeared with severe cramp-like pains. Second period did not appear for two months; she had more flow than at previous menstruation, the pain being a trifle less. The treatments in the meantime were continued every third day. After six months there was little change so far as her symptoms were concerned. Upon examination there was a decided improvement in the development of her uterus.

These three will give in a general way the results so far as the twenty individual cases are concerned, and so far as this particular condition is present, probably two out of three are much improved; the other third, so far as their symptoms, no better. In all these cases, after two or three months treatment there was improvement in the local condition or development.

The next series of cases embraces five patients on whom celiotomy was done, four of these for removal of the appendages, one a hysterectomy; all of these returned with severe pain in lower abdomen. The cases in which the appendages were removed referred their pains largely to the ovarian region, either one or both sides. Several of these were known as our regulars, having been coming almost every three or four days for a year; no doubt feeling as many of these patients do, that they are the wards of the hospital in which they have been operated on.

The history of several of these cases is as follows:

Mrs. H., removal of both ovaries for tubo-ovarian abscesses, one year previous. Pain in both ovarian regions, especially on the right side. Both stumps were found to be tender, so much so that she would cry out with pain upon the slightest pressure over this region. Having exhausted all resources, both local and otherwise, pelvic massage of twenty minutes since every third day was advised. The patient was much better after the fourth treatment, and after a dozen treatments all tenderness and soreness had disappeared.

Mrs. W., the hysterectomy case, was operated on eighteen months ago for commencing malignant disease of the fundus and had been a frequent visitor at the dispensary, complaining of severe pain and soreness all over lower abdomen. Examination revealed tenderness and soreness throughout the pelvis,

otherwise everything normal. Physiologic senile changes were apparent. As a last resort pelvic massage was advised and at this date she has only had six treatments. The tenderness and soreness is slowly but surely disappearing.

The other three patients, like so many dispensary cases, drop out if they feel a little better. Neither of these had over three or four treatments and we know little as to the result so far as they are concerned; one of them reported and said she was well.

Another interesting case in this group was Mrs. R., aged 27 years, married three years, sterile, complaining of severe pain on sexual connection, so much so that she has become melancholy and unhappy because of her inability to discharge the marital relations satisfactorily to herself or husband. The uterus was found sharply anteverted, with great tenderness over the uterosacral ligaments; otherwise negative. This patient gave a history of having had a dilatation of the cervix, pessaries and all sorts of treatment. Pelvic massage was advised as a last resort and as an experiment. After a dozen treatments of twenty minutes duration every third day this patient reported for examination, when all tenderness had disappeared and the marital relations were most satisfactory.

In a summary of the results obtained thus far from pelvic massage at the Gynecean Hospital, there can be no hesitancy in stating that in selected cases of undeveloped infantile conditions of the pelvic organs it deserves first consideration. There may be cases of this class in which, from a moral standpoint, it would be better not to advise it; but to condemn a treatment which offers prospective good simply because there is an occasional one whose perversity or frowardness would be against its use is, to say the least, contrary to that liberality of medical men who have always accepted those truths which are founded on practical results.

In tender stumps, after removal of the appendages, and indeed after all surgical measures for inflammatory or chronic pelvic disease, where there remains a certain tenderness with or without adhesions, provided sufficient time has elapsed to overcome these conditions, which would contraindicate massage anywhere, it offers a promising field.

In old exudates, the result of pelvic cellulitis, etc., it is worth a trial. In one instance, good results were obtained where all other measures failed. In anteversion with tender uterosacral ligaments, or in any general pelvic tenderness without inflammatory pathologic conditions and associated, as many of these cases are, with painful coitus, pelvic massage offers the most promising results, as three of these cases have verified.

In the cicatricial tenderness which sometimes follows plastic operations, it acted very satisfactorily in one case.

In simple uncomplicated endometritis it only increased the leucorrhoea and appeared to do more harm than good.

In subinvolution complicated, as these cases mostly are, by endometritis, it increased the discharge, aggravating the endometrial condition, which continued the subinvolution.

In retroversion, with or without adhesions, it gave negative results; and in one instance where there were firm adhesions, uterus fixed, it greatly increased the lumbosacral pains as well as other reflex symptoms.

In fibroid conditions it stimulated them to more rapid growth, and increased the menstrual and intra-menstrual discharge.

In tubo-ovarian disease, chronic or inflammatory, or any inflammation about the appendages, it is capable of doing much harm.

One important point noticed in most of these cases

was that the massage increased intestinal peristalsis, and produced a regularity of the bowels which was unknown to most of these patients without large doses of cathartic medicines.

It is to be regretted that sufficient time has not elapsed to speak advisedly as to the reliability of this treatment in sterility. But it is not too much to say that the satisfactory increase in the condition of the organs dependent upon pregnancy has been such as to give us encouragement in this unfortunate condition. One of these cases, in which sterility has existed and in whom there is marked improvement in the development of the uterus and regularity of the menses, has missed one menstrual period, associated with other signs of early pregnancy.

It has been noticed that, in a number of these cases, there was a concomitant condition of hemorrhoids, which were relieved in every instance. Whether this was due to the increased intestinal peristalsis producing a normal action of the bowels, or by stimulating these veins to greater activity, as well as the increased cellular changes taking place in the infiltrated connective tissue surrounding the rectal veins incident to the massage, is a question to be answered only in a further study of its value in this condition.

1433 Walnut Street.

FORMALDEHYDE AS A PRACTICAL DISINFECTANT.

Read before the Johnson County Medical Society, Sept. 8, 1897.

BY WALTER L. BIERRING, M.D.

PROFESSOR OF PATHOLOGY AND BACTERIOLOGY, STATE UNIVERSITY OF IOWA, IOWA CITY, IOWA.

The study of disinfectants and disinfection is of interest to all who are concerned in the preservation of public health. Recent years have afforded the means of placing this study upon more of a reliable and scientific basis. Frequent observation has noted the fact that although a certain disinfectant may be possessed of active germicidal properties in the laboratory, where it can generally be brought in direct contact with the microbe, it often fails signally when applied on a larger scale or for practical purposes.

Recently formaldehyde has been brought forward with considerable enthusiasm as a disinfecting agent, and the series of experiments embodied in this paper were directed toward determining to a certain extent its utility in this respect. In connection with a cursory review of the existing literature on the subject, an effort has been made to draw into comparison the several agents and substances heretofore used more prominently. Formaldehyde (formal, formalin) is the aldehyde of methylic or wood alcohol and appears on the market as an aqueous solution representing 40 per cent. of the gas. For some time it has been known to the biologist and the pathologist as a fixing, hardening and preservative agent of superior value. Since 1888 its germicidal properties have been recognized and of late have had extensive practical application. As a disinfectant it is used in three forms; aqueous solution, moist vapor and pure gaseous state. In the liquid form the standard 40 per cent. solution can be diluted to varying strengths and the dilutions as generally expressed refer to the commercial formaldehyde rather than to the pure gas itself.

To determine its germicidal properties a number of tests were made with the organisms bacillus anthracis (sporing) and staphylococcus pyogenes aureus. Addition of formaldehyde was made to bouillon tubes

in strengths of 1 to 3000, 1 to 2000, 1 to 800, 1 to 500, 1 to 200 and 1 to 100, inoculated from virulent cultures of above-named organisms showed no growth in any case, control cultures being made in every instance. Addition of formaldehyde to virulent bouillon cultures produced death of the organisms in ten and fifteen minutes, and subsequent sub-cultures showed no growth. It would seem from this that solutions of 1 to 200, 1 to 500 and 1 to 1000 would be appropriate for disinfection surgical instruments. Scalpels left in these solutions as long as twenty-four hours showed no tarnish or apparent change in the cutting edge.

As a deodorant I have found solutions of 1 per cent. effective in removing all vestige of odors from putrefying meat. Dr. K. Walker¹ has sterilized and removed all odor from feces by a 10 per cent. solution in ten minutes. Disinfection by means of moist vapor, while highly effective in a small amount of space, has not been proportionately successful when applied to a larger area.

The vapor of formaldehyde is produced by saturating cotton or cloth with a 40 per cent. solution, placing it in a shallow dish and covering all with a bell jar; infected substances exposed to this vapor are sterilized in short time. The experiments of J. J. Kinyoun² show that cover slips spread with staphylococcus pyogenes aureus, bacillus diphtheriæ, bacillus typhosus and sporing bacillus anthracis were destroyed in ten minutes. In applying this method to large areas the difficulty of so arranging the evaporation as to reach all parts of the room and the rather slow diffusion of the moist vapor has retarded the adoption of this method on a more extensive scale.

Formaldehyde in the pure gaseous state has shown itself to be by far the more satisfactory agent for the disinfection of rooms and wards. The gas is produced in two ways: 1, by generation from wood alcohol; 2, by the heating of commercial formaldehyde in an autoclave or special boiler to three or four atmospheres pressure and then allowing the gas to escape. The first procedure being carried on by means of lamps or generators, of which there are a number of different kinds in use; the Tollens, Gambier and Krell type prevailing in Europe, while the Hollister and Moffatt generators are being extensively introduced by their respective makers in this country. Two sizes of the Hollister lamp are manufactured, being designated respectively as No. 1 and No. 2, the first having a capacity of one quart of wood alcohol, converting the same into formaldehyde gas in twenty-four hours, while the No. 2 generator holds four quarts and uses up the contents in twenty hours. To operate, the platinum decomposing gauze is heated to redness, after which it is placed in the dome opening where sufficient heat is generated by the decomposition of the mixture of methylic vapor and air as it comes in contact with the gauze, to maintain the incandescence, which is kept up until all the alcohol has been converted.

The first tests were made with the No. 1 generator in a room 12 by 13 by 14 feet, capacity 2184 cubic feet, in which were two windows and one door, with very little leakage.

Test objects.	Exposure, 16 hours.	Exposure, 24 hours.
Cover slips spread with B. anthracis	Growth in bouillon after 24 hours' incubation.	Growth after 48 hours' incubation.
Staphylococcus pyogenes aureus.		
B. diphtheriæ		
B. of typhoid.		

Control cultures were made in each case to test the vitality of the organisms.

Test objects.	Exposure, 16 hours.	Exposure, 24 hours.
Gauze and cotton infected with pus from surgical kidney.	Growth after 24 hours' incubation.	Growth upon agar plates after 48 hrs. permitted separation of staphylococcus pyog. aureus and bacillus coli communis.

The last-named infected objects were placed in different parts of the room, one piece being suspended three feet above the lamps.

Disinfection was negative and the conclusion drawn that the space was too large for the size of the generator, so the next tests were made in a smaller room, having the dimensions of 7 by 8 by 10½ feet, or 588 cubic feet.

Test objects.	Exposure, 17 hours.	
	After 24 hours' incubation.	After 72 hours' incubation.
Cotton infected with Staphylococcus pyogenes aureus.	No growth.	No growth.
Cover slips spread with Staphylococcus pyogenes aureus.	No growth.	No growth.
Bacillus anthracis (sporing)	No growth.	Growth.
Bacillus of typhoid	No growth.	No growth.
Bacillus diphtheriæ	No growth.	No growth.
Bacillus mallei	No growth.	No growth.
Cover slips spread with Staphylococcus pyogenes aureus	Growth.	Growth.
Bacillus of typhoid		
Bacillus diphtheriæ		

Agar plates inoculated with the following.	After exposure agar tubes were inoculated from the plates and with them placed in the incubator.	
	Exposure, 14 hours.	Exposure, 21 hours.
	72 hours' incubation.	72 hours' incubation.
Bac. anthracis.	No growth on plates.	No growth on plates.
	Growth on agar sub-culture tubes.	Growth on agar sub-culture tubes.
Bac. diphtheriæ	No growth on plates.	No growth on plates.
	No growth on agar sub-culture.	No growth on agar sub-culture.
Staphylococcus pyogenes aureus	No growth on plates.	No growth.
	No growth on agar sub-culture.	No growth.

A second lamp, No. 1, was placed in the room and one test made while using two lamps, as follows:

Test objects.	Exposure, 15 hours.	Exposure, 21 hours.
	72 hours' incubation.	72 hours' incubation.
Cover slips spread with B. anthracis.	Growth.	Growth.
B. diphtheriæ.	No growth.	No growth.

Disinfection was accomplished in all instances with the exception of the active sporing organism of anthrax and wherever any slight concealment of the test objects was made. The last series of tests with the No. 1 generator were made in a very small space in order to determine its utility for surgical sterilizing purposes. This sterilizing chamber used for the purpose was made from an old metal hot air sterilizer, the lamp being placed under it and the chimney passing through an opening cut out to fit the same. Dimensions of the sterilizer, 13 by 17 by 12 inches.

Test objects.	Exposure 10 min.	Exposure 15 min.	Exposure 20 min.	Exposure 30 min.
Gauze soaked in bouillon culture of				
Staphylococcus pyog. aur.	Growth.	No growth.	No growth.	No growth.
Bacillus of typhoid	Growth.	No growth.	No growth.	No growth.
Bacillus diphtheriae	Growth.	No growth.	No growth.	No growth.
Bacillus anthracis	Growth.	No growth.	Growth.	Growth.
Staphylococcus pyog. aur. in four				Growth.
B. of typhoid } lay'rs of				Growth.
B. diphtheriae } apron.				No growth.
Ligatures soaked in bouillon culture of				
Staphylococcus pyog. aur.	Growth.	No growth.	No growth.	No growth.
Bacillus diphtheriae	Growth.	No growth.	No growth.	No growth.
Covers spread with

Bacillus diphtheriae	No growth.
Bacillus pyocaneus	No growth.
Gauze soaked in bouillon culture of	
Bacillus diphtheriae	No growth.
Staphylococcus pyogenes aureus	No growth.
Covers spread with	
Bacillus of typhoid	Growth.
Staphylococcus pyogenes aureus, concealed in the inside of a coat	Growth.

The second method of generating the aldehyde gas, introduced by Trillat, consists in the use of an autoclave or special boiler. The form of autoclave devised by Trillat is slightly different from the one ordinarily used for sterilizing purposes, with superheated steam. The autoclave used in connection with the following experiments is of the Rohrbeck (Berlin) type and was formerly used in the laboratory for sterilizing work. The formaldehyde, 40 per cent. solution, is placed in the copper container, with the addition of a neutral salt, such as chlorid of calcium in the proportion of 4 to 5 per cent., the heat is applied from below, the cover being fastened down firmly; when the manometer indicates a pressure of three and one-half to four atmospheres the escape tube is opened and the gas issues forth, as a dry vapor, with remarkable force and diffuses very rapidly throughout the room. The autoclave may be operated in the room that is to be disinfected, or it can be placed on the outside and the gas conducted by means of a connecting metal or rubber tube through

the keyhole or opening made in the door for the purpose. The last-named way is decidedly preferable for the operator, as the irritating inhalation of the gas is avoided. Test No. 1. Room 588 cubic feet, autoclave in the room, 300 c.c. of formaldehyde used.

Test objects.	Exposure, 12 hours.
Covers spread with	
Staphylococcus pyogenes aureus	No growth.
Bacillus anthracis	No growth.
Bacillus diphtheriae	No growth.
Staphylococcus pyog. aur.	concealed
Bacillus diphtheriae	by 4 layers
Bacillus of typhoid	of towel.

Test No. 2.—Room 3498 cubic feet, autoclave operated from the outside, one liter of formaldehyde solution used.

Test objects.	Exposure, 20 hours.
Covers spread with	
Bacillus diphtheriae	No growth.
Bacillus of typhoid	No growth.
Bacillus of plague or pest	No growth.
Bacillus anthracis	Growth.
Staphylococcus pyogenes aureus	No growth.
Bacillus mallei	Growth.
Staphylococcus pyog. aur.	Growth.
Bacillus of typhoid	covered by
Bacillus diphtheriae	five layers
Bacillus anthracis	of towel.
Bacillus of pest	Very faint growth.

In connection with these different tests, auxiliary observations are noted, illustrative of the various properties of formaldehyde and having direct bearing on its power as a disinfectant. Pieces of cloth stained with fuchsin were changed to a violet or purple color by exposure to the aldehyde. Egg albumin is slowly coagulated. Small cubes of gelatin are rendered insoluble in warm and hot water. When larger blocks of gelatin stained red by the addition of a few drops of fuchsin solution were cut open, the depth to which the change in color to violet or purple extended served as an indicator of the penetrating power of the aldehyde.

The gas as evolved is of an intensely irritating character, especially so to mucous membranes, yet when given an opportunity to escape, the room becomes habitable in a very short time. After the disinfection of rooms and apartments the atmosphere is now generally neutralized by means of ammonia vapor. Trillat and G. Roux found that guinea pigs exposed for twenty-four hours to a saturated atmosphere, neutralized as afore mentioned, suffered no ill effects.

An analysis of the air made in a room adjoining the largest one used in these experiments, gave a result of 2,600,000 bacteria to the cubic meter, while in the room of 3498 cubic feet, after an exposure of twenty hours (Generator No. 2), the examination revealed 1260 bacteria to the cubic meter. In the experiments of Trillat and Roux an analysis of the air showed a complete sterilization with the autoclave method, but a small number always retained their vitality after the use of the methylic-alcohol aldehyde generators. These same observers found that, in the examination of the dust, the samples collected from the walls gave no growth, while in the scrapings taken from the floor a certain number of bacteria developed after the use of either method. It was further noted that the larger collections of dust produced a cloudiness in bouillon sooner and more frequently than the

smaller or finer particles. Moist dust was also found to be more difficult to sterilize than when in the dry state, all of which tends to illustrate, to a certain extent, the penetrative power of formaldehyde.

The foregoing personal experiments seem to confine success in sterilization to superficial objects. Whenever an attempt was made at concealment of any degree, the result was in all instances negative. This agrees with the experience of Trillat and G. Roux, Bosc,⁵ Vaillard and Lemoine,⁶ Pfuhl⁷ and Ascoli. The results obtained are commensurate with the size of lamp or apparatus, that is, the amount of aldehyde gas generated and the size of the room. As to the amount of gas necessary for thorough sterilization this seems rather difficult to determine with any degree of exactness.

In generating the gas from methyl alcohol, Pfuhl has estimated the amount of wood alcohol to be used for every cubic meter as follows: bacillus of typhoid, sterilized by 47.1 grams; bacillus of diphtheria, sterilized by 21.2 grams; staphylococcus pyogenes aureus, sterilized by 62.8 grams; bacillus of anthrax spores, not by 94.1 grams; bacillus of tetanus spores, not by 94.1 grams. Taking these figures as a guide it would require not less than 2 liters of wood alcohol for 1000 cubic feet of space.

In the autoclave method where the 40 per cent. formaldehyde solution is used, Paul Strüver⁸ places the required amount at 8.2 centimeters of formaldehyde (40 per cent.) for each cubic meter (35.28 cubic feet), while the Marine-Hospital Service Circular No. 121 fixes the same at 14.4 c.c. per cubic meter. With these standards accepted the negative results obtained in the above named tests would be explained.

The conclusions naturally drawn from the results must be that small generators or lamps, such as the No. 1 Hollister and others of similar type, are not adapted for room sterilization, and should be confined to use in very small areas of space. The No. 2 generator, having a capacity of 4 quarts of methyl alcohol, should only be used for room sterilization, and then I would place the limit at 2000 to 2500 cubic feet; if larger space is to be disinfected, more lamps should be added in proportion.

Articles in the room should be exposed freely, clothing spread about, pockets turned inside out, and all concealment avoided as much as possible.

The cheapness and the little attention required in producing formaldehyde gas from wood alcohol, renders this method very desirable, but the use of the several forms of apparatus so far proposed is attended by quite a number of defects, which are mainly due to the fact that the slow conversion of the alcohol allows the gas to escape through the many crevices and openings necessarily found in every room, before it has had an opportunity to penetrate into the depths of substances contained in the apartment. The latter difficulty is overcome to a certain extent by the autoclave method of generating the gas; the reports of its use are certainly more promising. The rather high cost of the apparatus will interfere somewhat with its general introduction, but by this method the gas escapes under a high pressure and in corresponding larger amount, the diffusion is more rapid and sterilization, in consequence, more complete.

In the recent able article of Doty,⁹ on "Disinfection by Steam," the virtues of this agent are brought forward most forcibly, corroborating what has been known heretofore of its effective power when used on

a smaller scale; and although here, also, expense enters as an important item, there can be no question that in penetrative power, rapidity of action and especially in the sterilization of linen, blankets, bedding, etc., steam can not be displaced by formaldehyde. All observers concede the superiority of formaldehyde gas over sulphurous oxid for room disinfection.

As a sterilizing agent for surgical purposes, an alcohol gas generator may be used, when confined to space not exceeding two and one-half cubic feet, and used for instruments only, with an exposure of at least thirty minutes, for I question the practicability of its use for sterilizing sheets, towels, gauzes or dressings of any kind. Used in solutions of 1 to 200, to 1 to 500 it forms a most efficient agent for the disinfection of instruments, and is superior to carbolic acid or corrosive sublimate, having no injurious effects, nor is it disagreeable to the hands of the operator. As a deodorant and disinfectant for general purposes, when used in solution, it has no equal.

THE LIMITATIONS OF FORMALDEHYDE IN DISINFECTION.

BY ELBERT W. ROCKWOOD, M.D.

PROFESSOR OF CHEMISTRY AND TOXICOLOGY, STATE UNIVERSITY OF IOWA.
IOWA CITY, IOWA.

If formaldehyde or formic aldehyde is to be extensively used as a disinfectant, as now seems probable, it is important that the medical profession should know its limitations as well as its power, since either the use of a worthless disinfectant or the improper use of a valuable one is but little removed from a criminal act. Recent experiments indicate that only under certain conditions can we be reasonably sure of destroying pathogenic organisms by means of formaldehyde.

The compound is a gas of which the specific gravity is very nearly that of air. We should expect, therefore, that it would be slow to diffuse where air must be displaced. Pfuhl has shown (*Zeit. für Hygiene*, Vol. xxii, p. 339, Vol. xxiv, p. 289) that where it is present in sufficient quantities it sterilizes the surface of exposed objects, though its penetrating power is small. Similar results have been obtained by other experimenters. It is doubtful, then, whether it will replace other methods of disinfecting bedding, heavy clothing, etc. It has also been experimentally proven that a definite per cent. is necessary in the air to destroy bacterial life. Strüver (*Zeit. für Hygiene*, Vol. xxv, p. 356) places this at 1.6 grams of the gas in 1 cubic meter of space. He has shown too that the ordinary type of lamp used for the generation of formaldehyde by the action of platinum on the vapor of wood alcohol converts only about 8 or 9 per cent. of the latter into formaldehyde (loc. cit.). If a lamp is used for the production of the gas, it must be large enough to furnish the required per cent. to the air of the room. Moreover, since the formaldehyde has the same specific gravity as the air, it will diffuse at the same rate as the air is driven out of the room through the cracks and other openings. In order to be most effective not only must a large amount be generated, but this must be quickly done to prevent diffusion

We can thus explain the failures which have been reported with small lamps. Trillat's method of generating the gas by driving it out of its solution by heating the latter under pressure in an autoclave, avoids the difficulty by setting free the gas very quickly.

Formic aldehyde (CH_2O) is a gas under ordinary conditions, but it may be changed into a solid form. This is called paraformaldehyde or tri-oxymethylen. Its formula is $(\text{CH}_2\text{O})_x$ and it may be considered as condensed formaldehyde. It is an imperfectly crystalline substance which is volatilized by heat. The density of the gas thus formed shows that the complex molecule has been decomposed and the simple one, CH_2O , formaldehyde, formed. This method of generating the gas directly from the solid, which takes place at a not high temperature, is likely to prove the most practical means of producing the disinfectant without the use of expensive apparatus as in Trillat's method.

A GLANCE AT SOME RELATIONS OF DENTISTRY TO GENERAL MEDICINE.

Presented to the Section on Stomatology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY GEO. F. EAMES, M.D., D.D.S.
BOSTON, MASS.

The average dentist not only fails to recognize many indications which call for systemic treatment, but fails to see his need of such recognition. He still jumbles medical terms. His practice is largely empirical. He sees in part, but acts as one comprehending all; he gives advice to his fellow practitioners more freely than he would if he knew more.

If a new drug is advertised he tries it a few times, and immediately writes an article on it. He treats all forms of pyorrhea by scraping the teeth, but the deposit continues to accumulate, and the scraping is repeated. He treats sensitive dentine by the application of obtundents, and never dreams of prophylaxis or the correction of the underlying cause.

The teeth under certain conditions decay with great rapidity, and extra dollars are received for extra plugs inserted. The teeth are stained and eroded, only to be met with more plugging, and the mechanical removal of the stain.

During a persistent and alarming hemorrhage from the socket of a tooth, the heart is allowed to go on thumping against the chest wall, thereby resisting the local styptic, and tending to increase the hemorrhage.

It is still true, in too many cases, that a tooth is extracted solely because the patient asks that it be done. Many dentists still ask the patient what kind of filling they will have inserted, little thinking that if in certain cases the request is complied with the dentist may be sued for malpractice.

The dental college with its required three years' course and Latin entrance examinations, still continues to let loose thousands of graduates whose spelling and use of ordinary English is execrable, and whose understanding of the principles of pathology and medicine is practically *nil*. These go out to practice on humanity.

Shortly after I had begun to study dentistry, I was introduced by my preceptor to a very prominent minister who said, "so this young man is going to learn to haul teeth!" My preceptor wisely answered, "that,

among other things." Those "other things" have engaged my attention ever since, and there are and ever will be, other things to follow, for if there is one characteristic of the marvelous advance which dentistry as a profession has made, it is the great number of new relations which have been discovered to exist, not only between it and other branches of medicine and surgery, but relations with the arts and sciences.

It has been said that the dentist's daily work is largely mechanical; many make it so; many see only the mechanical side of it; for example, an operator may be engaged in plugging a large distal cavity with gold, but may not realize the fact that in some cases of nervous susceptibility, the entire organism may sympathize with the local irritation thus produced, to the extent of shock, or nervous collapse. What is the position of the mechanical operator in such a case? In his failure to recognize the vital connection of the teeth with the human organism he has failed to discharge his full duty to the patient, and is guilty of criminal neglect.

A dentist may be called upon at any time to exercise his medical knowledge immediately, in cases of nervous spasm, hysteria, syncope, shock, collapse, foreign bodies swallowed, poisoning, hemorrhage, etc.; or in a more leisurely way in the consideration of questions relating to stomatitis, adenoid vegetations, malignant growths, operations during pregnancy, and the various inflammatory conditions of the dental pulp and pericementum.

But there are other fields which have not been so fully explored, and which are vital to the interests of our profession. Teeth are being lost at an alarming rate on account of the ravages of pyorrhea alveolaris, so called, and this fact alone calls for deep medical research, for a thorough physical examination, including the blood, the salivary and renal secretions, followed by appropriate treatment.

In some of my recent cases the personal history has shown no indications of disease, when an examination of the secretions has shown conclusively the existence of abnormal conditions. This shows the necessity of a thorough examination, without regard to the patient's answers or knowledge of his condition.

In order to do this a most thorough study of the theory and practice of medicine is absolutely required. I can see no other way to meet these pathologic conditions in the mouth, believing as I do that they are the expression of some diathesis or other general disturbance. As medical specialists we are facing the serious problem of saving thousands of teeth which at the present time are being lost in spite of the great advances which our profession has made, and it rests with us, as members of the representative medical body of the United States, to use every means in our power to secure the requirement of a broader general and medical education as one of the essential conditions of graduation. If this be accomplished, the holder issue of recognition in any medical organization, and the dental profession will stand for one of the most profound and philanthropic agents of the healing art.

Eye Protector. The *Journal d'Hygiène* of March 10 describes an extension for the eye-glasses of bicyclers, etc., made of celluloid or some similar substance, which clamps over the eye-glass and extends to enclose and fit tight over the entire orbital region, preventing the entrance of dust or wind, although ventilated at the side.

SOCIETY PROCEEDINGS.

Physicians' Club.

Regular meeting held April 4, 1898.

Dr. E. J. DOERING in the Chair.
The subject for discussion was the

PROBLEMS OF ADOLESCENCE.

Prof. JOHN DEWEY of the Chicago University spoke on the
PSYCHOLOGY OF ADOLESCENCE.

He confined his remarks chiefly to some of the more commonplace aspects of the normal psychology. He considered adolescence as a normal manifestation in the development of life, and that the bulk of things which accompanied it should be regarded as normal, however excited or disturbed the individual might be at the time. He said a good deal of work has been done in recent years in the study of some of the details of the psychology of adolescence, from which many facts have been established. Reference was made to the theory of the emotional changes advanced by a Danish psychologist. The emotional changes which took place were marked characteristics of the psychology of adolescence. The physical changes that were going on made themselves felt throughout the entire organs. The nutritive changes were very marked during the oncoming of puberty. At this time there were many new sensations, especially organic sensations. These organic changes accompanied a physiologic reconstruction of the individual in his attitude toward others and formed a physical basis and stimulus for the immense emotional and intellectual changes accompanying the emotions. There could be little doubt as to the intellectual changes which took place, in which the individual brought to account the changes in his sensations and emotions. He felt differently. He felt more emotional toward others. A change was induced in the current of his thought, and it was necessary to bring his thoughts into harmony with the great flood of new sensations and feelings which were pouring in upon him.

Dr. M. P. HATFIELD discussed

THE PHYSICAL PENALTIES OF ADOLESCENCE,

in which he made an eloquent plea for greater development of the physical side of the individual during this period. He was compelled to confess that the London *Lancet* did not do a reckless thing when it offered a prize of £100 to anyone who could bring into its office a child whose ancestors had for two previous generations resided consecutively in the city of London. A third generation child could not be shown in Chicago for chronologic reasons. President Eliot of Harvard had said that "the future of the American child depends on getting out of the city into the country during the summer." If this was a fact what was to become of the majority of the children in Chicago? What chance was there for growth, for flowering, for blossoming, because adolescence in its best and highest form was a blossoming of perfect beauty. He believes that every child born into the world has an inalienable right to clean, warm clothes and proper food. It ought to come from the parents or State or from somewhere. Dr. Hatfield then spoke of the necessity of city children having more sunlight, purer air and, if possible, more healthful and hygienic surroundings.

THE ETHICS OF ADOLESCENCE.

WILLIAM M. SALTER—The meaning of the phrase is, I suppose, how shall we treat adolescence? For adolescence is a fact, a natural fact and does not admit of regulation itself. But we can decide how we shall treat it. The nature of this great change and some of the dangers connected with it have already been described. I have thought perhaps it might be best for me to take up or suggest one way of meeting one danger. The danger I have in mind is the familiar one, that the peculiar physical impulses and passions that arise in boys and girls at this time shall run away with them. The question is, how shall we meet it? The policy of many, perhaps of most, seems to be to ignore the subject. There are so many difficulties and embarrassments in dealing with it that most parents and teachers prefer to let it alone. They don't know what to say. Possibly they think it is a subject over which there ought to be a veil. They are not quite sure that these are proper things to talk about with children any more than for people to talk about with one another. And so they do little more than trust and hope, not without anxiety sometimes, that things will come out well. I suppose that it is in this happy go lucky way that most children are brought up; we think they can't do much worse than their fathers and mothers did.

A second way is simply to say that certain things are wrong,

to command or forbid, without explanation. On occasion those most reluctant to refer to the subject may be obliged to go as far as this. They rest their appeal on authority, adding perhaps invisible authority. They think children ought to obey and ask no questions. It should be enough for them to know that such and such things are proper, are what good children do, that other things are shameful. I would not ignore the sphere of authority or undervalue obedience. I think it is a good habit, but I think gradually the reason for all obedience should be made known and children learn to be self-directing.

A third course is to take the children into our confidence.

Children often ask the question where they come from, sometimes at a very early age. I saw a father who was troubled by questions of this sort from a 4-year-old. Ordinarily we evade the question or tell some pretty myth. I would suggest the advisability of dealing more fairly and frankly. I believe that in general it is well to give the children the natural explanation of events, not that I object to the stories and myths that are often told, but I think they should be told as stories, and that when a child is serious and wants to know the real explanation, the real explanation should be given. I don't believe in tricking or fooling children, and I think that the reaction on their own nature is bad. So with a child's question as to where life comes from. I would suggest giving up to the measure of the child's capacity of receiving (and that is determined largely by the extent of its questioning, of its unsatisfied curiosity) and understanding of the elementary truths of biology, in making it see that the human species is but one branch of the great tree of life. In simple language I would point out that there is nothing peculiar in the way human beings are born. Every living thing has seed somewhere on it or in it, and each successive living thing in turn comes from a seed. A plant was once a little seed, and so with the biggest kind of tree, and so was a bird, or a horse, or a man. Everything starts from beginnings so small that they are hardly visible, and the beginnings are always in the body of the parent. Every seed is at first nourished, protected there until it is far enough on to have a life of its own, and its leaving the body of the parent is what we call (at least in the case of most animals and of men) birth. Every little boy or girl was once born; before that it was carried and fed and kept out of harm's way in its mother's body; since, it has been out in the light of day and is learning, or should be, ever more and more to care for itself. Moreover, I would explain that seeds do not always grow of themselves. Two of them, we may say, for I need not stop here to make fine distinctions, ordinarily unite and become one, before either comes to anything. Sometimes the two seeds are in the same body; most commonly they are in two separate bodies, but they have to come together for either to really live and grow. So of the same sort of being there are what we call the male and female, each having its own kind of seed; but both are necessary, and the two must come together that any seed may grow and become in time a fish or a bird, or a human being. And so I would say to a child, we have fathers and mothers in the world, and among men we call fathers and mothers husbands and wives, because they live with one another and stay by one another and take care of one another, and at the same time take care of the children born to them.

In some simple, unsentimental, matter-of-fact way like this I should answer the child's question as to where he or his baby brother or sister comes from. I say I; I mean the parent or trusted teacher. Making a mystery of the matter is the last thing I should do, for unsatisfied curiosity easily makes one morbid and as a matter of fact, owing to the thoughtlessness and prudishness that are so common, there are probably more morbid boys and girls and morbid men and women on this subject than on almost any other under the sun. I would have this information given to a questioning child long before that critical age when the child is passing into manhood or womanhood, and new thoughts and feelings are stirred and new temptations naturally encountered. Before the passions arise let this information be given in a cool, scientific, perfectly objective manner, and much of the danger of this transitional time may be avoided. I know that well-meaning people sometimes deprecate curiosity on this point. They speak of an "improper opening of children's minds." They seem to almost regard it as another sign of children's natural depravity. But the depravity, I fear, lies elsewhere. Why is this an improper subject? Why is it not as sweet and clean as any other? Why is not birth a holy thing, and motherhood and fatherhood an equally holy thing? Reverence for a thing and a sense of its uncleanness are, it seems to me, incompatible feelings. I plead for a healthy, natural reverence for this sacred relation of life, and real reverence is based only on knowledge and understanding. And those who can not bear

to talk of this subject to their children should not forget one thing, that there are those who are quite ready to talk about it (though it be in whispers and on the sly), and that a normally constituted boy or girl is apt to get some sort of a notion of the truth, even though a distorted one. If we do not give the information in open, honorable fashion, it will be got in ways that are dark and disgraceful. An educator, after saying that this knowledge exists in two forms, the one "scientific, true and clean," and the other "morbid, false and dirty," adds a fearful statement that at least nineteen-twentieths of American children draw their information from the latter sort of knowledge. In back alleys, he says, on the way to school, in the servants' rooms, or from an older comrade they master this forbidden lore. Whose fault is it? I don't wish to bring any railing accusations, and I know how helpless and confused many parents feel, and yet I think the evil is more to be traced to the ignorance and prudishness, the mental and moral incapacity of the average parent than to any other cause. Parenthood is a task, I might say it is a profession, and one should bring one's wits and all the wide-awake sympathy and loving thought one can command to the discharge of its high and sacred duties.

In a word, I would have children understand life, then the law of life. The law of individual conduct follows as a matter of course. I would say to boys and girls, you have functions fitted to certain uses; hence they are for those uses: to make other use of them is wrong. Both self-abuse and sexual connection (save between husbands and wives) come thus to be abnormal things.

I know not whether, in this way, we can really meet the danger connected with adolescence which I started out to consider. Things are complicated in this world, and when we find one sound and wholesome method of procedure, it does not follow that it will always have the result desired. Wise education is something that requires infinite tact and the co-operation of a great many factors. And yet I believe what I have suggested is one true and normal line of action, and if we follow it, we may at least help in meeting our difficulty. If we are full of reverence ourselves before the great facts and laws of life, we can hardly fail to communicate something of it to our children. And reverence is the deep central need of life; the feeling that we have something else to do in life than to follow our temporary caprices or pleasures, the sense of a law above them. In childhood and youth is a happy time to sow reverence, but reverence must be based on knowledge. That reverence never dies out, not with the oldest man.

LYING, STEALING AND KLEPTOMANIA IN ADOLESCENCE.

Dr. W. X. SUDDUTH—Embryologists tell us that the child, in its development from the ovum to maturity, passes through all the stages of evolution that the race has experienced in its development from monad to man. If this be true, and my own observations confirm the statement, then in the life of the child we may expect to find reproduced the life history of the race, not only as to changes in form, but also as to evolutionary changes in mind and morals as well.

While the intra-uterine life of the child represents the vegetative stage in the development of the race, its birth ushers in the animal stage of existence, which extends to the period of moral awakening into the fully developed soul. The age at which children attain moral responsibility varies greatly in different individuals, peoples and countries. Some never attain it, others only in an imperfect degree, while in others it seems to be innate. Much depends upon prenatal influences and early environment.

While it is true that conscience is inherited and may be denominated the moral instinct, yet it is such an intangible quantity that it is very hard to define. The conscience of the present age may not be the conscience of a previous age or civilization. Conscience in one country differs very greatly from the same moral instinct in another country and clime. At best it is a very flexible article, and is largely the product of environment and education, and yet even the cannibal has a code of ethics which to violate he considers immoral, and in savagery there are also degrees of moral responsibility.

Admitting, for the sake of argument, that most children in our day and generation are born into the world with some degree of conscience which may lie dormant until called above the threshold of consciousness by life's experience, we must still admit that the child, in the first few years of its life, even in the most refined and enlightened environment, only too plainly demonstrates its uncivilized and animal nature. It has to be taught inhibition of bodily function through repeated and often painful experiences, and the most frequently used word in the vocabulary of the nurse or mother is "don't," "don't," "don't do what your animal nature tells you to do."

And thus, through more or less constant repression, the child is brought under the restraint of civilization, and becomes an orderly citizen. If his animal nature rebels and he absolutely refuses to become civilized, he is classed as irresponsible or incorrigible and is sent to the asylum for the feeble-minded or to the reform school. The nursery and the schoolroom, however, are the first institutions into which the young savage is introduced, and, excepting the curtailment of physical liberty, the discipline is often as strict as it is in state institutions.

Admitting the truth of the premise that the child is born into the world in a state of savagery, nude, not only as to person but as to morals, and that introduction into civilized society is a process of education which covers a longer or shorter course of instruction, and that the final accomplishment largely depends upon the ability and skill of its instructors to meet the varying individual idiosyncrasies of its animal nature, we are prepared to take up the breaches of ethics under discussion in this paper, viz., "lying" and "stealing." Before, however, we proceed to treat of their manifestation in the child, let us briefly consider the question as related to its more or less remote savage progenitors, and see whether we can not find in the past history of the race some excuse or partial palliation for the much-to-be-deplored traits of character found in some children.

In primeval times, and in the wilds of Africa today, savage man knows no law but that of "self-preservation" and "the survival of the fittest." Even in the lower forms of life these laws are universally operative at the present time, and deception by mimicry and subterfuge is the most effective means of defense of the weak against the strong. Even the bird will feign to be wounded, and utter the most painful notes, to distract the attention of the enemy from her young, and draw it to herself, if haply she may preserve their lives. "Playing possum" is not confined to the opossum alone, but is a common trait in all forms of life, and is considered justifiable and ethical when found in nature. But when the human weakling, placed by no volition of his own in so called civilized conditions, resorts to subterfuge and deception, adding verbal deception to that practiced by the lower forms of life, he is called dishonest or a plain liar. Again, when a hungry animal, man included, in a state of nature takes food where he finds it, even if it be from his neighbor's garnered store, he is simply following out the God-given instinct of self-preservation. It may have to pay the penalty of its depredations with its life, but even taking of life, in a state of nature, is not considered immoral; it is only the practical application of another of God's laws, viz., the survival of the fittest. But when a hungry child or man, following this same law, is detected in taking food from his neighbor's store, the act is called stealing, and if the quantity taken is sufficient, he is adjudged a criminal and sentenced by the law to imprisonment in jail or reformatory.

Laws are but the expressed mandate of the strong against the natural tendencies of the weak, in following out their God-given instincts; or, in other words, they are rules made by the most powerful element of society; for power at the present time is measured by property interest; hence our stringent laws against depredation on property even when done in pursuance of nature's law of self preservation.

The term "stealing" is applied to the taking of property by the poor and needy, either for the alleviation of their immediate wants, or to satisfy a desire for gain, in imitation of their more fortunately situated neighbor, who, when making depredations upon the goods and chattels of his fellow man, is spoken of as a "speculator" or a "dealer" on the board of trade; or if he "lifts" goods from the counter of the tradesman or the dinner pail of his fellow, goods for which he has no immediate use, such act is designated by the more euphonious term of kleptomania.

Aside from its purely biological aspect, however, this question is one of deep sociological import. Let us first consider the question of lying: Generally considered, lying is "a criminal falsehood," an intentional violation of truth, or an intentional misstatement of facts. Now, facts have as many aspects as there are individual observers of them. It is impossible to know anything *per se* in and of itself. It is only by comparisons more or less abrupt that we can know anything. We could never know cold, except we had felt its opposite, heat. We could never know light except we had been in darkness. We could never know pleasure except we had experienced pain. We could never appreciate truth except we had met falsehood. And so we might go on throughout the whole category of facts in nature. To speak the truth about any experience or fact in nature, requires an intellectual grasp of the subject in its entirety, and the mental capacity to draw logical deductions therefrom. Human nature is essentially original, and is instinctively antagonistic to rule. The personal equation is the greatest question that the student has to face in the study

of man. Individuality, which means originality, and imitation, or, as Sids puts it, suggestibility, are the opposite poles of human nature. While, however, man is an imitative animal, and therefore to a great extent a creature of environment, yet, by reason of his innate originality, he constantly works variations into his experiences or his facts which give them the flavor of untruthfulness. This is evidenced in every phase of human experience, even the simplest, in which there is no advantage to be gained by misrepresentation. This is well illustrated in the game of "gossip," for instance. Any number of people may participate in this form of mental diversion. The leader makes a statement to his immediate neighbor, who repeats it to the person next to him, who in turn passes it on to the next one, and so on until it is retold to the original speaker. By this time it is generally so modified and varied by the personality of those taking part as to convey a widely different meaning from the words first spoken.

Then, again, man is an imaginative animal, and his constant tendency is to clothe his images, which are subjective creations or experiences, with objective garments through verbal relation or expression. If these tales do not happen to tally with our experience, we say, "Ah, he is building air castles, or he is lying," when in fact we often are the ones at fault and the day-dreamer is the prophet of the future. The ideal is the real, and the vain, impractical ideas of the dreamer of today often become the verities of the future. But, you say, you are evading the real point at issue, lying is intentional misrepresentation. Admitting that this is true, it is still absolutely necessary to consider the question in all its bearings, so that we may have an intellectual comprehension of the motive that actuates the individual, in order to determine whether he is guilty of an immoral act, or simply has exerted a too free play of the imaginative faculty. Imagination is a subjective gift, and is normal in childhood, poets, musicians and inventors. It is only abnormal when it invades the domain of the objective and begins to jeopardize the interests of property. The child in the nursery clothes its paper dolls with important personalities, and prattles away by the hour regarding the wonderful experiences and doings of the Mesdames Vanderbilt, Astor and Gould of their mimic world; and yet we encourage it up to the point where the little darling invades the outer world with its poetry, when it becomes immoral and reprehensible. And yet the child is only living out its true subjective nature.

A case in point came to my notice not long since. A precocious boy of five was intrusted for a brief time each day with the care of some cattle. On horseback he herded the drove on the prairies while the regular herder went to his dinner. He was admonished to be very careful not to let any stray away. It was an easy job, and having little to do he often drew on his imagination for entertainment. "What," he said to himself, "if some *big* men on fast horses should come and drive off some of the cattle under my charge," and in imagination he would follow them and demand the return of the stolen animals. From day to day these thoughts were his greatest delight. He dreamed and dreamed on these exciting experiences, until they seemed to be almost realities to him, and only required the right setting to make them real indeed. The time came thus: One night when the cattle were counted into the pound, one was missing. Willie was questioned and he recited with appropriate embellishment, the story of his day-dreams as to how *two great big men*, one on a black horse with flowing mane and tail, and the other on a white horse, oh, such a beauty! had come and driven off a *big red* steer. The more he was questioned the more tenaciously he clung to his story, adding points at each repetition until it became a veritable nursery tale, as such it proved to be, for on a recount in the morning the tally was found to be correct, a mistake having been made in counting the night before. Did the child lie? Who can answer! He may have been afraid of punishment for neglect of duty, and sought to shield himself by throwing the blame on the *two big men* who, he asserted, came and forcibly took away the supposed lost animal, and against whom he could not reasonably have been expected to contend. It may have been egotism, pure and simple, that craved the notoriety of the hour in being the center of interest. It may have been an hereditary tendency, directly inherited, to deceive. Who can tell! Who dare assume the responsibility to judge the child's mind and ascribe the motive that determines the condition!

Painters, poets and writers of fairy and other similar stories draw on their imaginations for their productions, and we grant them full need of praise. None think them immoral until they claim reality for their dreams. If, in following out the God-given instinct of self-preservation, or through lack of intellectual or moral perception, the claim of reality is made with the idea of personal advantage in the struggle for existence, then the conditions immediately change, the motives are impugned

and the culprits condemned as born falsifiers. When the weak following the purely natural instinct of self-preservation, resort to these methods, which are the only weapons they have against the strong, they are adjudged enemies of society and punished as criminals, or if it can be shown that they are not mentally responsible they are sent to asylums. The question, therefore, resolves itself down to this, that lying, stealing and kleptomania from a biologic standpoint, are the outcroppings of purely natural instincts, commendable in a pure state of nature, but greatly to be deplored in our present state of civilization.

If my premise is correct it seems to me that the rationale of treatment does not lie in harsh, unsympathetic measures of condemnation, in which the motives of the individual are impugned, but in a careful system of education looking toward the moral, intellectual and physical upbuilding of a child. The first step in this direction lies in a careful medical examination in order to ascertain whether there are any physical conditions existing that would place the child in the defective class. Defective sight or hearing has often caused an otherwise tractable, obedient child to become insubordinate and fall behind his fellows, he suffering the while mentally and physically because of his unrecognized deficiencies. Other physical defects have been known to produce similar results.

The second step in the successful handling of such cases is a sympathetic understanding of man's place in nature.

The third step involves a systematic exposition of the general principles of ethics, based upon biologic facts, in language so simple as to be readily grasped by the undeveloped mind of the child. It is surprising how freely the youthful mind will absorb even the most profound principles of ethics when logically and simply presented. In this system of education the child should be permitted, so far as possible, to be its own judge as to the degree of normal progress attained. Whenever it is practicable courts of justice should be established, officered by the children themselves, to which should be referred all the cases of infraction of the laws of ethics that occur within its jurisdiction.

Prof. COLIN A. SCOTT discussed the subject of
SCHOOL FATIGUE IN ADOLESCENCE.

He said fatigue was really the negative side of all work, of all effort. There was nothing accomplished anywhere by any sort of organization which did not leave behind it some trait or a small degree of fatigue. Reference was made to the recent work done in the experimental laboratories of psychology along this line and to what are known as "fatigue curves." He thought there were undoubtedly some individuals who had practically a chronic condition of fatigue, and it might be congenital in such cases. In doing the same kind of mental work one individual manifested fatigue much sooner than the other, due in part perhaps to weaker groups of brain cells, and hence a greater susceptibility to fatigue. One of the significant features of adolescence was the principles of generalization, and these were largely connected with sex. He could not wholly agree with Mr. Salter's method of dealing with children and telling them the plain facts about the sexes at an early age. He thought that sex would not be satisfactory unless clothed with a certain amount of mysticism, a sort of something which it was impossible to entirely penetrate.

Chicago Medical Society.

Regular meeting, held April 6, 1898.

The President, Dr. F. HENROTIN, in the Chair.

Dr. CHRISTIAN FENGER read a paper entitled

WHY I HAVE ABANDONED THE USE OF THE MURPHY BUTTON AND OTHER SIMILAR MECHANICAL APPLIANCES IN INTESTINAL OPERATIONS.

He had abandoned Senn's plates, partly because their application was complicated and required about the same time as suturing, and partly because he saw them cause gangrene, and cases were reported in point. He did not consider it necessary to include in the discussion the experience of other surgeons, as this could be gathered from the literature and was well considered and ably discussed by Jacobson. He considered his own experience ample to decide conclusively the principle involved, and he believed, furthermore, that this was a matter that could not be decided by statistics alone. It was immaterial how many cases were successful and how many were failures for a decision as to the fate of the Murphy button and other mechanical contrivances. Dr. Fenger then reported cases in detail in which the Murphy button was unsatisfactory. He drew the following conclusions: 1. Any mechanical contrivance based upon the occurrence of sloughing and gangrene is objectionable as it is beyond our power so to constrict the

gangrene that it will not overstep the limits of safety. 2. Any mechanical appliance that is non absorbable is objectionable because it may be retained indefinitely in the gastro intestinal tract, and may therefore be the cause of disturbances, and because it may be dangerous or impossible to remove the foreign body. 3. Mechanical appliances, whether absorbable or non absorbable, may cause fatal gangrene without limitation. The Murphy button I consider the most effective, the most dangerous, and I might say, the most brutal of them all in this respect. 4. I looked toward mechanical appliances with great hope for their usefulness, but after a fair trial for years I am gradually and reluctantly forced to give them up. 5. The surgeon who does intestinal surgery must learn to suture, to use the needle: first, on the lower animals until he becomes proficient. 6. I fully agree with Halsted when he says: "I believe that the license to practice general surgery should be withheld from those who have not practiced on animals the operations for circular suture of the intestine and intestinal anastomosis." If a surgeon has not acquired the skill of using the needle, he has no right to attempt this kind of work; he should leave it to his more experienced colleagues until he has acquired the necessary dexterity. 8. If an operation on the intestinal tract has already lasted so long that the final step of suturing would take so much time that the patient might be in danger of collapse from prolonged operation, then the operation may in many cases be more safely stopped temporarily and finished at a later time. 9. If we search for means to avoid the use of mechanical appliances, then means will be provided. The question of the valuable time saved by the use of the Murphy button and other devices has been overestimated. Take, for example, operations on the stomach. Haberkants, who has collected statistics of all operations on the stomach up to 1895, makes the following statement: "The mortality of operations on the stomach depends not so much on the age of the patient as on the nature and extent of the local disease. The duration of the operation has no influence upon the mortality as judged from eighty-nine total resections and sixty-six gastro-enterostomies. 10. Halsted witnessed an intestinal operation including circular suture. The operation required five hours for its performance, but was successful. This conforms to the opinion I have obtained from my own experience, that the element of time in operations is not of so great importance as one would generally be led to believe.

Regular meeting, held April 13, 1895.

First Vice-President, Dr. ARTHUR D. BEVAN, in the Chair.

Dr. ALEXANDER H. FERGUSON presented a patient upon whom he had operated, removing the inferior dental nerve through the mouth, for the relief of facial neuralgia. He expressed the belief that this operation could be done very easily and the graver operation of the removal of the Gasserian ganglion obviated in many cases. An operation upon the inferior dental nerve, if the neuralgia has commenced in that branch first, and it usually does, should be done and the nerve extirpated, and this could be accomplished through the mouth without scarring the face. Failing in this, the surgeon would have just cause for removing the Gasserian ganglion.

The second case he exhibited was also a patient upon whom he had operated a short time ago for tic douloureux, but in this case he removed the Gasserian ganglion.

A third case exhibited was one in which he did an intravertebral neurotomy of the posterior roots of the brachial plexus for neuralgia.

Dr. FERGUSON next presented a specimen of gall bladder and bile ducts, showing acute phlegmonous cholecystitis and gangrene of gall bladder, with perforation, causing abscess, peritonitis and death. No operation: postmortem made, and 776 gallstones found.

Under the name of acute progressive empyema of the gall-bladder Courvoisier in 1890 found only seven cases in literature. A few instances have been recorded since then. He had two reasons for presenting this specimen: 1. The rarity with which this affection occurs. This was the first case he had seen after an experience of fifty-six operative cases of cholelithiasis. 2. Early operation in gallstone cases and during the attack of biliary colic. At a recent meeting of the Society it was urged that an operation should not be performed during the attacks of colic, and in refutation of this teaching he showed the specimen and reported the following case:

Mr. J. W. S., age 59 years, merchant, of Syracuse, Ind.; on the 3d inst. was seized with biliary colic, and called Dr. B. F. Hay to relieve him. His pulse and temperature were normal: the pain was intense, only relieved by frequent hypodermic doses of morphin and local applications of hot moisture. A tender swelling, dull on percussion, was felt under the right costal arch. The liver dulness was enlarged and the organ

tender. He was not constipated. By the third day the paroxysms subsided, the tumor and tenderness remaining, as well as a dull, constant aching sensation. On the evening of the third day the smouldering pain became infuriated to intense seizures of suffering, causing him to complain even when profoundly narcotized with morphin and the abdomen covered with hot stupes. Slight tympany: a rise of temperature to 102 degrees F.; an increased pulse-rate of 110 to 120 per minute, and slight jaundice ensuing, impressed Dr. Hay with the grave condition of his patient, and called Dr. E. E. Ash of Goshen, to attend with him. The aggravated signs and symptoms tenaciously persisting, Dr. W. K. Mitchell of Ligonier was summoned in consultation. All were agreed as to the diagnosis of gallstones complicated with pending peritonitis, which proved to be only too true, and advised an operation. That surgical interference was not carried out in a comparatively early step of the disease, which would have been most likely successful, was not the fault of these gentlemen. Every easy movement, every fall of temperature, and every expression of the patient, of feeling better, raised the family hopes that an operation might be averted. On the sixth and seventh days the tympanites increased and extended over the tumor and lower border of the liver, the pulse and temperature remaining about the same (pulse 110 to 120, temperature 102.5 degrees). He was summoned on the seventh day, and on arriving found that he had died about half an hour previously. Dr. Mitchell, who closely watched the case the last twenty-four hours, kept an accurate record of the pulse, respiration, temperature, condition of the skin, pupils, stools, urine, medicine given, etc. During this time seventy-eight observations were recorded. The pulse ranged from 116 to 136; respiration 28 to 52; temperature 100 to 105.2 degrees F. The temperature was at its lowest degree an hour before death, and the highest ten hours previously, at which latter time, however, the pulse was only 120 and respiration 32. The pupils were constantly dilated, the skin moist except at midnight, when it became dry for a couple of hours, and then the temperature rose to its maximum. His urine passed involuntarily, and he was unconscious nearly all the time, only speaking distinctly once, eighteen hours before death.

Previous history.—With the exception of occasional slight and insignificant colicky pains in his stomach during the last two years, lasting but a few minutes, and never calling in a physician, he has enjoyed the best of health. Family history negative.

Postmortem. The findings in the abdominal cavity were as follows: A full length median incision allowed coils of distended bowel, normal in color, to protrude; upon passing the hand adhesions were felt in the right lumbo hypochondriac region, but nowhere else. A transverse cut through the right abdominal wall to the lumbar region fully exposed the pathologic condition. The right and upper border of the omentum was red, swollen, covered with thick lymph, overlapping the colon and gall-bladder, and adherent by delicate adhesions to these structures and to the parietal peritoneum and liver. An abscess was situated in the right lumbar region a little below the end of the twelfth rib, which contained about an ounce of pus. A suppurating tract led from it to a perforation in the gall-bladder on its anterior surface near the end. The edges of the perforation in the gall-bladder were black and gangrenous looking. The gall-bladder was about twice the normal size, tense and edematous to the touch, livid in appearance with black spots, showing through in many places. It had the manifestations of an advanced stage of acute phlegmonous inflammation. It was sausage shaped and extended along the under surface of the liver beneath the costal arch. The adhesions surrounding it were very friable, and these being broken down, dark colored fluid oozed from the surrounding tissues. The gall-bladder was now opened. It was filled with dark colored bile and 776 stones, varying from the size of half a grain of wheat to a large bean. The mucous wall of the gall-bladder was gangrenous in many places, which here and there showed through all the coats of the viscus. The ducts were laid open and found normal. All the other organs in the abdominal cavity appeared normal, even the vermiform appendix.

Bacteriologic examination. In Professor Klebs' laboratory at the Post Graduate, the contents of the abscess and the fluid contents of the gall-bladder were subjected to a bacteriologic examination.

Remarks.—Cholecystotomy performed early would most likely have saved his life. Waiting for the attack to pass off proved fatal, and this was his first pronounced attack. If infection is present, the sooner it is uncompromisingly attacked surgically and drained the better. In a well-marked case of biliary colic, let it be even the first attack, the gall-bladder

enlarged, tender, etc., he could see no scientific or reasonable objection to the removal of the gallstones there and then during the attack. Early operation shortens suffering, prevents complications, and in most cases obstruction of the ducts. No case should, in his opinion, be allowed to become chronic, early gall-bladder surgery is safe and easy, while late operations are dangerous and difficult. The physician has no assurance from clinical experience or pathologic findings that in a given case the attack of suffering will subside without causing: *a*, jaundice by obstruction of the common duct which may remain until relieved by a serious operation; *b*, rupture of the gall-bladder; *c*, ulceration and perforation by pressure of the stones; *d*, death by the severity of the colic; *e*, empyema, and *f*, acute phlegmonous inflammation and gangrene.

From clinical experience we know that it is utterly impossible to tell the sufferer the number and size of the stones or stones within his gall bladder, or what the outcome of his case may be. To advise a fellow-being suffering these torments to delay operation until the attack is over, in a clear case of cholelithiasis, is cruel and blind advice.

Dr. E. W. ANDREWS presented three cases of circular enterorrhaphy which he had performed by different methods. In one case he used Frank's coupler with a satisfactory result. The patient was 25 years of age, and had been in perfect health with the exception of an inguinal hernia. He was called to see the patient to relieve the strangulation. An operation was done and the intestine not only found to be gangrenous, but surrounded in the hernial sac by a quantity of pus. It became necessary to resect a section of the bowel, to resort to end to end anastomosis, and in this case he used the Frank coupler. Operation was done on Wednesday, and the coupler passed per rectum on the following Monday.

The second case was one in which he performed a circular enterorrhaphy by Monsell's method.

The third case was one of complete occlusion of the small intestine occurring in a man advanced in years, and brought to him in *extremis*, having a pulse of 140 or more, and vomited everything. An enterorrhaphy was made by the method of Monsell, followed by recovery. Microscopic examination showed adenocarcinoma of the small intestine. The three cases recovered.

Dr. EDWARD H. LEE showed a patient upon whom he had operated for renal calculus. He passed around a skiagraph showing a shadow corresponding not only with the location of the stone but with its size and form.

A second case exhibited by him was one of exophthalmic goiter. The enlarged glands were removed. He said authors differed greatly as regards operative interference in these cases. He agrees with Mikulicz that surgical interference should be limited to suitable cases. Stenosis in this case was so marked as to justify surgical interference. Extirpation should be done where possible on account of being easier than excision. He used the Kocher incision above clavicle, believing that it gives the best cosmetic result. He also reported a case of extrauterine pregnancy in which he had operated, and showed the specimen.

Dr. WILLIAM A. MANN exhibited a patient with tuberculosis of the eyelid. Sixty-two cases of this affection had been reported, and he presented the case on account of its rarity.

Dr. DAVID LIEBERTHAL exhibited an interesting case of scleroderma.

Western Ophthalmological, Otological, Laryngological and Rhinological Association.

Abstract of the Proceedings of the Third Annual Meeting held in Chicago, April 7 and 8, 1898.

(Concluded from page 986.)

Dr. W. H. BAKER of Lynchburg, Va., contributed a paper entitled

THE POLITZER AIR BAG,

in which he deprecated the universal, and too common, use of that instrument when the simpler and safer method of Valsalva could be employed with equal success, and much less danger to the integrity of the ear and its structure. The dangers to the integrity of the ear, when the method of Politzer is employed, are rupture of the tympanum, injury to the ossicles, labyrinthine hemorrhage, etc. He claims that there is no middle ground between the method of Valsalva and cauterization for the air-bag of Politzer to stand upon, and that what can not be accomplished with much more readiness and safety to the patient by the method of Valsalva, in the way of inflating, can only be accomplished by the aural catheter.

Children can easily be taught to inflate their own ears, thereby

avoiding the fright and disgust caused by the sudden, sharp blast produced by the air-bag, which is about as apt to force air into the stomach as into the middle ear, unless the child has been taught to pronounce the proper letter at the proper time, or swallow the water when told, which is as tedious a process, if not more so, as teaching the method of Valsalva.

The paper is a plea against the indiscriminate use of the Politzer air-bag.

Dr. W. SCHEPPEGRELL of New Orleans, read a paper on

THE NON OPERATIVE TREATMENT OF DISEASES OF THE UPPER RESPIRATORY PASSAGES.

The object of the communication is not to disparage the effects of surgical methods, but to emphasize the importance of non-operative measures and their usefulness in a large majority of cases. So many articles have been published on the surgical methods of treating diseases of the nose and throat, and in comparison so few on non-operative methods, that the former has assumed an undeserved prominence, so that many patients and even physicians believe that every pathologic condition must be remedied by surgical interference. The "six weeks' specialist" is especially dangerous in this connection; he has witnessed a large number of operations in the polyclinic, many of these cases having been especially reserved for these lectures, and he associates every case which he meets with surgical methods. He purchases the necessary instruments, and, on his return home, every patient is viewed with the possibility of utilizing this investment.

The limits of this paper permitted only of illustrating the principles of non-operative methods without going into details. The nasal septum does not require surgical treatment simply because it is slightly deformed; an operation is required only when it impinges into the opposite tissues, offers marked obstruction, or gives rise to reflex disturbances.

In the treatment of acute coryza, the author has had the best results from a spray of a 2 per cent. guaiacol solution, and the internal administration of quinin. The prescribing of cocain preparations in these cases is dangerous. There is no justification for placing this alkaloid in the hands of the patient, thus favoring the formation of the cocain habit.

The greatest surgical abuses in rhinologic practice have been in hypertrophic rhinitis and in the so called intumescent rhinitis. Congestion of the nose may be a sign of a disturbed condition of many other parts of the body, and these should be carefully eliminated before surgical methods are applied. The cases in which they are demanded will be found comparatively few.

In atrophic rhinitis, cleanliness is a most important factor in the treatment, and this may be best obtained by means of copious irrigation with non-irritating solutions. The methods that have been recommended are the various topical applications, sprays, massage, electrolysis and serum therapy. The location of the accessory sinuses makes the treatment almost necessarily surgical. It should not be forgotten that acute sinusitis naturally tends to cure. Exploratory punctures of the antrum are not without danger and may develop a purulent condition in healthy antra.

In nasopharyngeal catarrh, surgical methods are usually referred to the nasal chambers. It should be remembered, however, that certain constitutional conditions, such as lithemia, scrofulosis, etc., may here exhibit a local expression of a general dyscrasia. An important part of the treatment is to prevent the patient from irritating the pharynx by means of the *nasal secreta*, by means of which the secretion is drawn into the mouth and expectorated. A non-irritating solution should be given the patient as a means of freeing the nasopharynx, and all violent efforts on his part to clear the throat should be avoided. It should be explained to him that the sensation of the secretion in the throat may be due not only to its actual existence, but also to the increased sensitiveness of the throat, which would cause even the normal secretion to feel as a foreign body.

Hypertrophy of the faucial and lingual tonsils may exist to a considerable extent without giving rise to inconvenience, and as the tendency in these cases is to diminish with advancing age, the *laissez faire* plan is a good one, unless indications positively point to surgical interference. Operations on the tonsils are not entirely without danger, and the argument that the tonsils are of no service, and that their extirpation can cause no harm is one that we have no right to assume.

In regard to the larynx, while admitting the importance of the respiratory function of the nose in this respect, we should not at once assume that every defect in the throat is due to some abnormality of the nostrils, and still less that the condition must necessarily be improved by operative measures in the nasal chambers. Cases have been seen by the writer in which

the cautery has been applied so extensively that but little of the normal mucous membrane could be seen, thus destroying the glandular elements and inhibiting its capacity for supplying moisture for the inspired air. How the operator expects to benefit the larynx by these heroic methods, it is difficult to understand. The larynx may be affected by various conditions of other parts of the body, even the most remote, and the cause of irritants of all kinds should be removed. In a recent case the discontinuance of the habit of smoking twenty cigarettes per day cured a spasmodic laryngeal cough of long standing.

The nose and throat specialist should avoid the tendency of becoming narrow in his views and of seeing the patient only through the laryngoscopic mirror and nasal speculum. He should be as familiar with matters of general medicine as the general practitioner, and should make it his motto not to know less of general medicine, but more of rhino-laryngology.

BILATERAL ABDUCENS PARALYSIS.

Dr. WM. A. FISHER of Chicago—I present this case of bilateral paralysis, not as a common one, but as one of the most infrequent occurrence. Here we have not only paralysis of both abducens, but as much contraction as is possible, not only of the muscles that turn the eye inward, but of all the ocular tissues toward the nasal side. I would hesitate to present to this Society an ordinary case of unilateral abducens paralysis, for you all know how frequently they occur. In fact, I am rarely without such a case. At the present time I have three cases in my clinics all giving a specific history. This case shows what a great deformity can follow a paralysis of this kind.

The history of this case is as follows: Mrs. B., aged 50 years, married thirty years, has five children, three living and in good health; one died of measles and one of croup; father died at the age of 70 years, mother died at the age of 75. She has had three brothers, one died in the army in India; has not heard from other two for ten years, when they were in good health; six sisters, two died in infancy, others in perfect health. Thirty-seven years ago, or when she was thirteen, her left eye began to turn in. Previous to that time she was not aware of having any eye trouble. She consulted a physician in Ireland and was told her eye could be straightened by an operation. About twenty years ago, or seventeen years after the left eye turned in, her right began to turn. Six years ago she had la grippe, and since that time her eyes have grown rapidly worse. The last two years they have been about as we now find them. The patient has been a hard-working woman all her life, doing washing and carrying heavy baskets of clothes on her head. She is now in, and has always enjoyed good health. Vision is sufficient to enable her to get around where she is well acquainted; tension normal. The eyes were rotated so far inward that both pupils were hidden in the inner canthi. It was impossible to rotate either eye out under cocaine anesthesia. Not being able to get an ophthalmoscopic view, and knowing there could be no harm in an attempt toward straightening, and possibly some good result, the patient was anesthetized with chloroform and an effort made to rotate the right eye out and sever the offending tissues. It was impossible to rotate the eye outward to any extent, but an attempt was made to sever the internal rectus. Not only was it necessary to sever the muscles that rotate the eye inward, but it amounted to a dissection of all the ocular tissues toward the nasal side. The eye was fixed as firmly as in a case of panophthalmitis, and adhesions everywhere. A slight improvement was produced which lasted a few days; the pupil was free from the inner canthus, but no improvement in vision. Contraction has taken place and the eye is in about the same condition as I found it. The patient has never complained of pain in the eyes and gives no history of an inflammatory condition, but we have adhesions that could not have been produced by inflammation and the patient remained unconscious of it.

Hutchinson reports seventeen very interesting cases of ophthalmoplegia externa (Royal Medical and Surgical Society of London, 1879). In summing up his report it seemed certain that syphilis was the cause in ten of the seventeen; that in the remaining seven a reasonable suspicion of syphilis might be entertained in several. He further says, with such a fact in mind one feels that it is almost impossible to make the negative even fairly possible. The evidence which connects this affection with syphilis is exceedingly strong, and that which favors the belief that it can occur independently of it must be held to be open to some doubt. The cause of paralysis in this case is obscure. We can exclude some of the common causes, but syphilis should not be excluded, even if we have, as we do in this case, a negative history. As syphilis is given as the cause of nearly all these paralyzes, I have given her increasing doses of potassium iodid, and will continue for a reasonable time. It would be no more than fair to suppose the lesion in this case was caused by la grippe.

The following officers were elected for the ensuing year: President, J. E. Colburn of Chicago; first vice-president, Wm. W. Scheppegegrell of New Orleans; second vice-president, Casey A. Wood of Chicago; third vice-president, H. Gifford of Omaha, Neb.; secretary, Frank M. Rumbold of St. Louis; treasurer, W. L. Dayton of Lincoln, Neb. Place of meeting, New Orleans, La.

SELECTIONS.

Immediate Laparotomy in Wounds of the Abdomen.—A paper on this subject by Surgeon Caillet of the French Army was read by M. Chauvel at a recent meeting of the Académie de Médecine, the author having based his remarks mainly on two cases that were related in detail. In the first a non-commissioned officer received a revolver shot point blank in the lower part of his abdomen, and an hour later was taken to the hospital. The officer on duty dressed the wound with iodoform and applied a bladder containing ice. The following morning when Dr. Caillet saw the patient, six hours after the injury was inflicted, he was in a good condition, the temperature was 96.8 degrees F. and the pulse 80; there was no vomiting, hiccup or dyspnea. By 4 o'clock in the afternoon, however, unfavorable symptoms had set in and at 7:30 operative interference was decided on. Median laparotomy disclosed four perforations of the small intestines and the cavity of the peritoneum contained some doubtful looking fluid, with particles of food and false membrane. Recovery, which was delayed by an attack of pneumonia, took place in about six weeks, the missile coming away in a stool on the ninth day. In the second case a dragoon was stabbed in the left iliac region and immediately vomited some coffee he had just taken. Four hours later he was admitted to the Vincennes Hospital, his general condition being then satisfactory. There was no nausea and his pulse beat firmly as 70. An attempt was made to probe the wound, but the stylet could not be introduced. A perforation seemed uncertain; an expectant treatment was adopted and the next morning the patient was so well that he was allowed several spoonfuls of milk. A few hours after this a complete change took place and urgent signs of generalized peritonitis showed themselves. Median laparotomy was at once performed, but the patient was so weak that only the small intestine could be examined, the result being negative. The abdomen was then closed, after the cavity had been washed out with warm artificial serum. Shortly afterward the man died and at the post-mortem examination it was found that the large intestine had been pierced. The author believes that if preventive laparotomy had been adopted the patient would have been saved. There is no intrinsic danger in laparotomy nowadays, he says. Then why delay it even in the most doubtful cases? In the instances cited the impossibility of sounding the wounds contributed largely to the postponement of the operation; but considering the small sized projectiles now in vogue this method of establishing a diagnosis should not be accorded too much weight, especially when anesthesia has not been employed. Exploration is, no doubt, of great value where practicable, but inability to effect it is no proof of the absence of perforation. Statistics may be unfavorable to immediate laparotomy in penetrating wounds of the abdomen, but the author, nevertheless, maintains that it is generally indicated, and in this opinion he apparently has the support of M. Chauvel.

Alimentary Glycosuria.—Krehl has studied alimentary glycosuria occurring after beer drinking, and for this purpose he has examined one hundred students. He was able to vary the kind and amount of beer taken, as well as the time of drinking and the diet. The urine of four young brewers, who had drunk large quantities of beer in the fasting state or at breakfast time, was also examined, and in one case sugar was found. The exact composition of the beer, especially in regard to sugar,

was not ascertained. The students examined mostly drank one-half to two liters and a half of beer in the morning. Of fifty-seven drinking a lager beer, the sugar reaction was positive in four cases, or 7 per cent. In the case of an export beer, five out of fourteen, or 36 per cent., had glycosuria. In twenty-five students drinking one-half to one and a half liters of Rosen beer, no glycosuria was observed. Out of nineteen cases drinking large quantities of an Ehringsdorf beer in the evening, one, or 5 per cent., had glycosuria. Of eleven other students drinking largely of all sorts of beer, only one had glycosuria. It was often impossible to repeat the examination in these cases. The predisposition of the individual is always important in these cases, for those who drink the most are not always those who have the glycosuria. The more marked presence of the glycosuria in the morning was due to the more rapid absorption. Both Strümpell and Strauss showed that alcohol favored the appearance of an alimentary glycosuria. Perhaps the sugar in the urine in these cases was due to the action of the alcohol, but other substances in the beer may be responsible. The author thinks that at the present moment there is no satisfactory explanation of the alimentary glycosuria following upon beer drinking.—*British Medical Journal*.

Vaccination has Suffered more from Negligence than from Fanaticism.—The blessing which vaccination has conferred upon mankind will never be appreciated, certainly never heartily received, till smallpox shall have had an opportunity to demonstrate its unspeakable loathsomeness and death-dealing power in full epidemic swing and form. Antivaccination societies still exist in Europe and America, but the bait in converts which the fanatical fools who belong to these orders offer the Gorgon of smallpox is a bagatelle compared with the multitudes who are suffered carelessly to go unvaccinated, through loose sanitary regulations, or who are resting in fancied security given by imperfect vaccinations, or primarily perfect vaccinations whose protective power has been canceled by time. Vaccination even by the profession is often carelessly administered, while the laity presume to vaccinate without professional advice, and even give judgment upon the genuineness of the vaccine scar with the confidence of experts. Vaccination should never be done by inexpert hands. The source of the virus should be unquestionable, and the result should be carefully noted in every case. Nobody but an expert can pronounce upon the genuineness of the vesicle (any kind of sore or inflammatory lesion must not be allowed to pass for a vaccination), and revaccination should be insisted upon in every case after the lapse of five years from the time of the last successful vaccination. If vaccination and revaccination were made compulsory by legal enactment, and the above rules were carefully followed, smallpox would be stamped off the face of the earth in a decade. As it is, the disease lies in wait till the careless or unsuspecting victims become sufficiently numerous, and then begins the march of death.—*American Practitioner*.

Pure Diphtheria.—Dr. Barbier has communicated to one of the Parisian medical societies the results of an elaborate study of unmodified diphtheria. He thinks that he has demonstrated that cases of pure diphtheria, due to infection with the diphtherial bacillus only, were clearly distinguishable from cases of modified diphtheria in which the additional infection of other microbes, streptococci, staphylococci, etc., played a part. As a result he presented a clinical description of diphtheria much simpler and more definite than the existing one, which embraces all forms. This pure diphtheria may be observed experimentally in animals in which the bacillus causes simple vaso-constriction and necrosis but never inflammation. But when diphtheria occurs in man it is usually in the modified form, for being but feebly contagious a pre-existing morbid condition of the affected surfaces is generally necessary to enable the disease to install itself. The diphtherias secondary to scarlet

fever and measles are examples of this. In only fifty-four out of 221 cases examined bacteriologically was the diphtheria pure. Pure diphtheria is to be recognized clinically not by the appearance of the membrane but by the state of the throat especially; the mucous membrane is not inflamed, but on the contrary; rather pale mucous or purulent secretion is absent, and adenopathy is absent or trifling. The temperature is but little elevated; it is at most a little over 100 degrees or 101 degrees F., and this only temporarily. The pulse is always small and rapid. There is little or no albuminuria. However benign may be the appearance of the throat the patients look ill and have a pale, leaden complexion, because they are under the influence of the diphtheria toxin. No matter what may be the extent of the membranes or the multiplicity of the localities attacked, recovery under the influence of antitoxin manifests itself on the following injection and is completed in two or three days, rarely later. The prognosis is therefore very good. All Dr. Barbier's fifty-four cases, which included thirteen laryngeal cases in which intubation had to be performed recovered. There is only one danger in this form, extension of the disease to bronchi, which may lead to suffocation. Dr. Barbier never observed paralysis in any of his cases, a remarkable fact. In modified diphtheria of the throat the mucous membrane is always red, sometimes it bleeds and the tonsils are always swollen. The inflammation may be limited to the neighborhood of the false membrane, confined to a part of the mucous membrane, for example the uvula, or generalized. In the pharynx is seen mucopurulent matter, secreted there or coming from the nose or larynx. In almost all cases the lymphatic glands are enlarged. Though the appearance of the membranes is not characteristic in most cases, and especially when there is staphylococci infection, they are rather thick and extensive, and often the odor of the breath indicates decomposition which is caused by saprophytes. The nose is almost always attacked, and whether membrane exists or not there is a discharge, serous, purulent, or hemorrhagic, containing numerous septic microbes. The temperature is higher than in the purer form 101.3 to 104 degrees. Complications such as bronchopneumonia, otitis and impetigo frequently occur, and in the worst cases septicemia.—*London Lancet*, February 19.

PRACTICAL NOTES.

The Success of Oxygenated Serum in Cold Abscesses is announced by E. Luton, who recently proclaimed its value also in diffuse psoriasis. He makes injections of a mixture of 75 grams of a 10 per cent. solution of sodium phosphate with 25 grams of oxygenated water at 20 volumes.—*Sem. Méd.*, March 9.

Ichthyol Spray in Acute Catarrhal Laryngitis.—The throat is sprayed with a 2 per cent. aqueous solution of ichthyol which the patient inhales twice a day, not inhaling too profoundly, for fear of producing nausea. The spasmodic cough and hoarseness soon disappear, as was also the case in several cases of false croup.—*Sem. Méd.*, March 19.

Wolkowicz' Method of Operating Muscular Wry-Neck.—The muscle is cut from the front, high up, obliquely downward to the back, and the lateral edge of the upper stump sutured to the medial edge of the lower part, leaving the medial part of the upper and the lateral part of the lower ununited. In this way the muscle can be lengthened as desired.—*Cbl. f. Chir.*, March 12.

Initial Symptoms of Osteomalacia.—The bones become sensitive to pressure, especially the spine in the lumbar region; paralytic troubles in the muscles of the pelvis and thigh; subjective disturbances of an ostealgic or neuritic nature. Fine results have been obtained with 1 to 5 centigrams phosphorus to 100 grams cod-liver oil. One teaspoonful three times a day.—*P. Rissmann, Cbl. f. Chir.*, March 19.

Terralio is the name given to a new salve base which has all the advantages, and more, of the usual salve bases, with none of their disadvantages, we are informed. It is made of a mixture of calcium sulphate, ustum; kaolin; terra silicium; lanolin; glycerin and the antiseptics. In consistency like lanolin, but more plastic, it is readily washed off with pure water, which adapts it for cosmetics, etc., besides its important therapeutic uses.—P. J. Eichhoff, *Deu. Med. Ztg.*, 19.

Ulcer of the Foot, according to Schulte, is not caused by inflammation of the tendons or periosteum as generally accepted, but is due primarily to a fracture of the second, third or fourth metatarsal bones. In fifty-nine cases he has examined, a callus was always distinctly to be felt, and radiographs in many cases confirmed his opinion. Crepitation and abnormal mobility was noted in six cases. His treatment is rest in bed, massage, moist bandages, and later, painting with iodine.—*Cbl. f. Chir.*, March 19.

Keratitis and Conjunctivitis may be treated with massage and a sublimate-cocain salve. Sasseparel has found the following salve, followed by gentle massage through the closed lids, for a minute or two, extremely effective in cases of phlyctenular keratitis, ulcers of the cornea, chronic conjunctivitis and episcleritis; cure in ten days at most: Five per cent. sublimate solution, one drop; cocain hydrochlorate, ten centigrams; vaselin, four grams.—*Sem. Méd.*, March 19.

Connection Between Nasal Affections and Psychiatry.—C. Ziem urges a more active treatment for certain mental disturbances, and traces the connection between them and nasal troubles, especially affections of the accessory cavities, determining disturbances in the circulation of the frontal region of the brain. His communication in the *Monats. f. Ohr. k.*, 1897, 11 and 12, describes his own personal experience with scientific candor and accuracy, and is a convincing plea in favor of the alleged connection.—*Cbl. f. Chir.*, March 12.

Neurasthenic Hunger.—Neurasthenic individuals sometimes experience peculiar attacks resembling fainting spells, with extreme weakness, pallor, vertigo, cold perspiration, weakness and trembling in the knees and a sense of heaviness in the head. T. Benda describes one patient thus affected every afternoon toward night. He noticed that in many persons hunger accompanied the attacks and assuming that they were due to exhaustion from lack of food, combined with autointoxication from food in the intestines which the neurasthenic stomach had hastily passed along in a more or less undigested condition, he found that he could cure them by having the patient eat something, and prevent them altogether by small frequent meals.—*Deu. med. Woch.*, March 31.

Unna Shaves off Soft Chancres after congealing the entire surface with ethyl chlorid, applying the razor flat and slicing off a layer 2.5 to 3 mm. thick, which he states removes all the germs. He then touches the raw surface with the caustic pencil, powders with iodoform and covers with an oxid of zinc dressing, renewed every day or two. If there are several chancres he treats each in the same manner, but takes off a slice 3 to 4 mm. thick in neglected and serpiginous chancres. The rapidity of the cure, often in less than twenty-four hours, the simplicity of the post operative treatment and the absence of the consecutive scar recommends this method above all others, except when the location of the chancre, at the orifice of the urethra for instance, forbids its application.—*Sem. Méd.* March 23.

Cocain as an Analgesic in Dermatology. Unna applies it before scarifications, etc., in a powder; cocain hydrochloric, one-half to one gram; magnesium carbonate ten grams. A moist compress is laid outside, for ten minutes, which the patient is instructed to press lightly against the part. If the skin is intact, pure basic cocain must be used instead, or the surface

can be painted with the following mixture: Pure cocain, 1 to 2 grams; Hoffmann's solution, 50 grams; collodion, 1 gram. It can also be applied in the following form: Pure cocain, 1 gram; sweet almond oil, 50 grams.—*Sem. Méd.*, March 9.

Ichthol Salve in Measles.—The favorable effects obtained by rubbing the body with ichthol salve in variola, suggested the same treatment for measles and if it can be applied from the very first, it aborts the infection; neither eruption nor fever appears and the child recovers promptly, if the eruption is already apparent, with hyperthermia and bronchitis; the temperature returns to normal after one or two rubbings, and the patches grow pale and disappear. In four or five days the cure is complete, when a warm bath is given to remove the traces of the salve. He has the salve rubbed in all over the body, morning and night; thirty grams of ichthol to ninety grams of lard.—A. Strizovere; *Sem. Méd.*, March 10.

Surgical Operations on Hysterics and the Insane.—From a study of 111 cases of ablation of the uterus and adnexa, Angelucci concludes that mental disturbances are not favorably affected by these operations. Only 17 were improved; 25 hysterics were rendered much worse; 44 hysterics became insane; 2 nervous patients, confirmed hysterics, and 23 were not affected either way. He therefore asserts that hysteria is a counter-indication for gynecologic surgical operations, and they should only be attempted when absolutely necessary, and then combined with suggestion, although he concedes that occasions may arise when a simulated laparotomy may be resorted to as a suggestive measure after all other therapeutic means have failed.—*Rev. de Psych.*, February.

Speedy Cure of a Long-Standing Case of Borborygmus.—Veire has reported a case of a girl, aged 15, who for more than two years has been troubled with borborygmus. The noises were so loud that they could be heard in the next room. After an attack of borborygmus had continued several hours a great quantity of gas would be brought up and for a short time the noises would cease. Veire made a diagnosis of ectasia and ptosis of the stomach. He prescribed a close-fitting bandage. A month afterward the patient stated that from the time when the bandage was first applied the noises and formation of gas had entirely ceased.—*Bulletin Général de Thérapeutique*.

Evisceration and Shock in Abdominal Surgery.—L. Tixier's monograph is based upon long experience with Fochier, Ollier, Poncet, Jaboulay and Pollosson, and extensive experimentation on dogs and tests on the cadaver. He states that in all operations performed on account of fresh contusions and penetrating wounds of the abdomen, a rapid evisceration for the purpose of obtaining information is imperative, if the operation follows soon after the injury and there are no adhesions nor meteorism. In chronic ileus it is less urgently indicated, but if deemed necessary it can be done, as the intestines are not very sensitive except during acute exacerbations. In acute occlusion, when the seat of the trouble is unknown, complete evisceration is much to be preferred to drawing out the loops separately, if the operation is prompt. In tardy operations the intestines have become too sensitive and an artificial anus is recommended by many, if there is no internal strangulation nor invagination. Evisceration is to be avoided in acute peritonitis, unless necessary to locate a fresh gastric or intestinal perforation. In tuberculous peritonitis it is indicated in order to increase the curative effect of the simple laparotomy. With a certain amount of meteorism the incision in the linea alba is preferable, but if the intestines are flabby they can be eviscerated through a lateral incision. He finds that a healthy peritoneum in dogs does not react with shock if the evisceration does not last longer than ten or fifteen minutes, while the reflex phenomena appear at once and are very severe if the peritoneum is inflamed or otherwise injured. Dry gauze produces much more violent reflex action than warm moist gauze. He therefore advocates moist asepsis; also ether narcosis.—*Cbl. f. Chir.*, March 26.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, APRIL 30, 1898.

MILITARY MEDICINE OF THE DAY.

From many sources it is learned that smallpox is now rife in Cuba, and many have expressed uneasiness lest the new levies of troops, many officers and men alike inexperienced, might suffer from smallpox. The assumption is a gratuitous one, for without question all State troops will be vaccinated at the different State rendezvous. This vaccination and revaccination so far as the militia are concerned, need not be done until the men are mustered into the United States volunteer service, as many of them will doubtless have to return home after the rigid physical examination which the regulations require. The percentage of loss is considerable, but their places can easily be supplied from among the thousands awaiting opportunity for enlistment, but while at the rendezvous awaiting orders to the field, the entire force should be properly vaccinated, or revaccinated as required in individual cases. In this war the United States should not lose a single man from smallpox. So far as yellow fever is concerned, let it be repeated that the open mountain country is safe. It is the infected houses and the foul drains, stagnant water and crowded tenements, filth and confined air, that furnish breeding places for Yellow Jack. The alcoholic and those enfeebled by disease, have least resistance, and soonest fall victims.

The code of hygienic rules just published by Surgeon-General STERNBERG fully meets the present requirements.

Havana can be made as healthy as any city in the tropics, if it were thoroughly policed, and the infectious centers dealt with as would be done in our own cities. The talk of dredging the bay is senseless. The only feasible plan to purify the bay is to build the long-talked of canal to establish a current, to destroy

the wooden infected wharves, and build stone sea walls. Then with sanitary attention the city could be made clean. This plan however costly will be effective and economical, if we consider the vast losses inflicted upon the world in the past.

The Spanish government has never pretended to disinfect houses, to destroy fomites, to purify the stagnant arm of the bay, or the festering wharves, but on the contrary has thus for centuries been *particeps criminis* in sending death-dealing microbes throughout the world. There has however been no unkind discrimination. Spain has kept on sending sick troopers into the old infected military hospital, with utter indifference, and the offspring of the grandee who came to sit at the taxgate suffered the same fate as any other non-immune. What Great Britain has done with Kingston may be easily repeated in the Cuban cities if the Cuban authorities, when they control, will bend their energies to that end.

THE "INSANITY DODGE."

It is notorious enough that the plea of insanity in criminal cases has fallen into popular discredit and the term "insanity dodge" is characteristic of the common notion, in this regard. That this popular idea is to a certain extent erroneous is also true enough, though it may not be so easy to convince the average layman of the fact. Indeed the very cases that have made the plea unpopular may be and often are the ones in which it is most justly urged; the public furor for the execution of some imbecile or paranoiac whose crime has especially aroused popular reprobation not infrequently doubly blinds justice and leads to what is hardly morally better than lynch law under its forms. Sir JAMES MACKINTOSH or whoever else it was that made many years ago a rather formidable charge of judicial murder against the then existing English law on this account would were he living still find many instances in modern practice in this and his own country to warrant his accusations.

On the other hand it must be admitted that the plea is far too often utilized to aid undoubted criminals to escape the due punishment of their crimes. This has been the more easily accomplished by the aid of the very proper feeling that it is better to let the guilty escape occasionally, rather than to risk the unmerited punishment of an irresponsible and legally innocent individual. The fact also that there has been no legal standard of medical expertness has been an important factor in the production of the miscarriages of justice in either direction; the opinion of the skilled alienist has counted for no more than that of any other medical witness however really unqualified he may have been in this particular specialty. The result has been in this particular specialty. The result has been to bring all expert medical testimony into discredit and as a profession we have suffered.

To remedy this state of affairs by legislation has so far seemed a difficult task and it can not be claimed that the efforts in this direction have anywhere as yet been a brilliant success. Legislators are hard to convince on a point where their prejudices can be aroused against the desired measures and they are more than ever liable to be suspicious of what may seem to them to be legislation in favor of a single professional class. The "one man as good as another" idea has to be combatted to some degree in effecting such legislation, and its political bearings and possibilities are ever present in their minds. It is somewhat of a satisfaction therefore to find as we do that in one State at least a little advance has been made by judicial decision and where legislation has failed, judge-made law has stepped into the breach. According to an editorial in the *Chicago Tribune* of April 21, the supreme court of Iowa has decided that whenever a question is raised as to the sanity of the defendant in a criminal trial, a special trial for insanity shall be at once ordered and if insanity is found to exist by a jury of medical experts, the individual is sent to the insane ward of the penitentiary for an indefinite period. If on the other hand he is found sane the question is considered disposed of and the criminal trial proceeds. The editorial account does not state whether or not he is under particular surveillance in the insane ward and that there is any further report made as to his mental condition. It would be a manifest injustice to commit an individual as yet unconvicted of crime to associate indefinitely with insane criminals, and the possibilities of *habeas corpus* suggest themselves as likely to be invoked very early in such a case. It would be equally unjust also and against good policy to have such a person let loose upon the public because the jury had made a mistake that was evident to the closer observation of the prison physician, or because another judicial opinion has been pronounced that he was unjustly detained. The solution of the difficulty is not perfect under such conditions; a notorious criminal might soon be pronounced recovered and, so far as anything is stated to the contrary, could be turned loose again upon the community. The better way would be, it would seem, to have the detention ordered for purposes of observation, and in case it should appear that the insanity was simulated or merely temporary since the commission of the crime, the person could, on his discharge from the insane ward, be tried for his offense in the regular way. Such a practice has been in vogue in times past in certain counties in Illinois, where on the appearance or claim of symptoms of insanity in a prisoner awaiting trial, he was sent to an asylum with a request that before his release the authorities should be informed so that they could take him out to stand his trial if thought proper. In this way no injustice was done in cases of genuine mental derangement, while merely temporary aliena-

tion or simulated insanity were no bar to final conviction and punishment for crime.

The decision of the Iowa supreme court is, however, an advance upon the old practice, under which it was possible for a clever criminal with an able counsel to sometimes escape punishment for offenses against the law. That this is or has been as frequent an occurrence as the public commonly believes, is very doubtful; there is generally at least some grounds for the plea of insanity when it is successful. The term "insanity dodge" is indeed applied more often to cases where the plea is perfectly legitimate than to those in which it is a subterfuge to defeat the law and help a sane criminal to evade the due penalty of his offense. The lunatic's criminal act is often more liable in fact to be such as will arouse public indignation and lead to a popular outcry for its punishment than is that of the sane and artful criminal, who is much more likely to act so as not to excite feelings that may be too dangerous for himself.

There are many in the so-called criminal classes who are so near the boundary of mental soundness as to make a plea of insanity in their case at least plausible. There are others again who are clearly over the line in some respects, and who yet may be more or less responsible for their criminal acts. The law, recognizing no intermediate stages between sanity and insanity as regards responsibility, creates infinite possibilities of injustice in special cases. The result is that our penitentiaries abound in cranks, while occasionally a rank criminal is turned loose unpunished for his offenses. The remedy, if there is any, is not to be found in railing at the "insanity dodge" or condemning lunatics alike with the sane criminals. A temporary commitment to the care of a skilled alienist diagnostician would be the best and most natural solution of the question, but this is apparently not always practicable under present conditions. We are still left to the discretion of judges and the fallibility of juries where legislation has failed to meet the demands of medical science and common sense in this important matter.

WITCHCRAFT EPIDEMICS IN THE UNITED STATES.

Some years ago the *Popular Science Monthly* devoted no little editorial space to what it called the recrudescence of superstition. In this discussion "Christian science," folklore medicine, charms, etc., were regarded as a revival of fifteenth century practices in the closing nineteenth century. In truth, however, these were simply atavistic survivals of prehistoric fetichism which had persisted in popular folklore. They were pushed to the front by accidental wealth-getting by people in the lowest grades of culture. Chicago, from its cosmopolitan population, is peculiarly liable to these fetichistic explosions. In Chicago demons are still exorcised from the insane-

by Italian ecclesiastics, as more than one medical superintendent of the County Insane Hospital has had reason to know. Germans of the lower rural middle class still believe in "magic trees." "Dr." Paul Wachter, an ex-barber was lately sent to the penitentiary at the instance of German politicians for pocketing money from them to put into a "magic tree" as a cure for ailments.

The "witch doctor" is still a potentate among the Pennsylvania Dutch. "Witch Doctor" Amend of Pittsburg, who died in 1894, earned till his death \$15,000 yearly for detecting witches. In three instances his advice, given along the old witchcraft-finding lines, nearly led to murder by an infuriated mob. The latest witchcraft epidemic in the United States has occurred in West Virginia. The defectives of large European cities were sold to certain planters of Virginia for a term of years and were allowed to redeem themselves at the end of these. Many of these redemptioners escaped to form the mountaineers of Virginia. Among this population has occurred the latest witchcraft epidemic. Near Lewiston, W. Va., four children of one family were seized with epidemic hysteria of a convulsive type. One was a 10-year-old boy and the others were girls aged from 11 to 15 years. Under suggestive cross-examination the boy claimed to be bewitched and charged an old man and woman with the crime. The local witch doctor declared that the child's accusation was well based. Effigies were made of the old man and woman and were shot at with silver bullets. The effigy of the old woman not being hit she was hunted into the forest during a wild storm and has not been seen since. The witch doctor then filled a bottle with needles, pins, and water and put it on the fire to boil. The first person who appeared after it began to boil and asked a favor was the witch. The old man who had previously been accused called to borrow some powder. He would probably have been killed immediately, but the bottle exploded, sending its contents into the assembled crowd, whose consternation permitted him to escape. The children still continued to have convulsions and the whole community became excited. Under their advice the father changed his witch doctor for another, who made grand preparations to work a potent counterspell which would take nine days to develop. Meanwhile the county authorities had heard of the disappearance of the old woman and sent Dr. DANIELS and Dr. HUMBLE to treat the epidemic. Under their careful management the convulsions of the children disappeared. Before this several other children had been attacked, some of whom had become so insane as to require hospital custody. According to Dr. HUMBLE, the belief in witchcraft is widespread in the community. One old lady described to him with all sincerity that a certain old woman had fatally bewitched her sheep and cows. The same

witch would have killed her son by spells had these not been neutralized by a witch doctor with powerful incantations.

Nearly all the "witch doctor" therapeutics here employed was gravely collected into a respectably bound and printed volume and published at Harrisburg, Pa., in 1853. This hoodoo pharmacopeia enjoys an interstate as well as a local reputation in Pennsylvania, West Virginia and Ohio. When such gross superstitions survive and even control newspapers (as witness the clairvoyant columns) through the editor being made such by accidental fortune, it is hardly surprising that the eighteenth century patent medicine man and the "specialist for every disease human flesh is heir to" should have such a prominent place in newspaper esteem. If it take so long to kill the witchcraft delusion which the medical profession (in the person of Dr. REGINALD SCOTT) scotched in the sixteenth century, the survival of the kindred delusions mentioned is hardly surprising.

PANCREATIC COLIC WITH GLYCOSURIA.

A few years ago when the results of a series of interesting experiments and pathologic researches were placed before the profession many physicians supposed that a frequent cause of diabetes mellitus had been found in pathologic changes in the pancreas; for extirpation of this gland produced glycosuria in animals, as does also serious disease of the organ which materially interferes with its function. Increasing experience has, however, shown that comparatively few cases of diabetes are dependent upon pancreatic lesions, for pancreatic disease is not common, and lesions involving the entire gland are still more rare. In connection with this subject the report of a case by POLIAKOFF of Moscow, in a recent number of the *Berliner Klinische Wochenschrift*, is of interest.

A man of 28 years, without any pathologic history, who had always been in good health, had suffered for a period of ten weeks, without apparent cause, from violent epigastric pain, chiefly felt along the border of the left ribs, near the vertebral column and radiating into the left hypochondrium. In the space of three weeks five attacks had been present, accompanied by vomiting. After these attacks the patient remarked that he was losing flesh, that he was feeble, but that his appetite was distinctly increased and that polydipsia was marked.

An examination at this time by Professor ZAKHARINE showed that the patient was suffering from distinct polyuria and that glycosuria was pronounced. Pressure over the kidneys and over the biliary ducts failed to produce any pain, but exploration of the epigastrium revealed a painful spot over the pancreas, or in other words just above the umbilicus. There was however no tumor. The wasting, pallor, dyspepsia, polyphagia and general feebleness seemed to make up

the diabetic complexus and because of the character of the pain and its position it was considered that the patient was suffering from a pancreatic colic, probably due to the presence of a stone in the pancreatic duct. Proper regulation of the diet so far as glycosuria and the development of calculi is concerned, caused a disappearance of the trouble so that no further return of the disease appeared during the following year, so that it is probable that the stone escaped into the intestine and that other stones were not formed which might produce similar symptoms. While a postmortem did not confirm the diagnosis in this case POLIAKOFF believes that it was undoubtedly one of pancreatic diabetes. It will be remembered, however, in this connection that in 1894, NIMIER, who had found pancreatic calculi at autopsy with alterations in the pancreas, asserted that such a find was not indicative of pancreatic diabetes, unless by a process of sclerosis a total obstruction of the glandular tissue had resulted. That is to say, the diabetic trouble only becomes constant when such glandular lesions result. In POLIAKOFF's case the mere temporary obstruction of the duct was sufficient to pervert the function of the gland so that temporary glycosuria resulted.

Naturally, there is much difficulty in making a differential diagnosis between pancreatic and hepatic colic. FRIEDREICH believes that such a diagnosis is almost impossible. On the other hand, LICHTHEIM has published a case in which he made a diagnosis with the following symptoms. Severe colic, with violent pain in the epigastrium, vomiting and fever, diabetes which continued for a considerable time, and a fatty diarrhea. Fatty diarrhea is not, however, a necessary symptom in making such a diagnosis, but the stool should always be watched and carefully examined in order that pancreatic calculi that pass into the intestine may be discovered. It is interesting to note in this connection that LANCEREAUX observed three cases of obstruction of the pancreatic duct out of fourteen cases of pancreatic diabetes; and that FREYAN has seen diabetes follow a calculus in the pancreas which the autopsy showed to have caused complete atrophy of the gland and that FLEINER has seen marked cardialgic pain in patients who had inflammation of the pancreas due to lithiasis.

CORRESPONDENCE.

Dr. Klebs' Ameba of Yellow Fever.

WASHINGTON, D. C., April 20, 1898.

To the Editor:—If Dr. Klebs had taken the trouble to read my report, published in 1890, he would have ascertained that he is not the discoverer of his supposed ameba. These bodies were first observed by Councilman in 1889, and for a time were believed by him to be parasitic amebæ, but upon making comparative researches this view was found to be untenable, as is shown by the italicised portion of the following quotation:

REPORT OF DR. WILLIAM T. COUNCILMAN.

"The most interesting results were obtained from the examination of the liver. It has long been held that fatty degeneration of this organ was one of the most characteristic lesions of yellow fever, and it was found to a greater or less extent in all of the sections examined. It varied greatly in intensity in the different cases; in some comparatively large areas of liver tissue, which showed very little degeneration, were found, in others only here and there a few normal liver cells were seen. This lesion, however, does not seem to me to be the most important one of the organ. When sections of the liver are deeply stained with eosin and subsequently with a nuclear stain, either hematoxylin or methylen blue, a very peculiar appearance results. When such sections are examined with a low power the liver cells are found to be stained a faint reddish blue or purple color, the nuclei being a deep blue or purple. Among the liver cells or in place of them a great number of bodies stained intensely red with the eosin are found when examined with a high power. These bodies are found to differ entirely from the liver cells. They are sharply circumscribed, are highly refractive, and are composed of a perfectly hyalin mass containing numerous vacuoles. Their size varies greatly; in some cases they are no larger than a leucocyte, in others as large as two liver cells. They are found inclosed in liver cells, otherwise perfectly normal, and in some cases they entirely take the place of these in the liver beam-work between the capillaries. In some cases examined they apparently made up the mass of the tissue, only here and there a portion of a liver cell or a nucleus of such being seen. Sometimes, especially where the liver tissue was most scanty, along with these definite circumscribed masses more or less granular material was found which stained in the same way. These bodies were generally round or more or less irregular in form. In some of the liver cells small hyalin masses staining in the same way were found which were not so sharply circumscribed as the larger bodies. They were found most abundantly in the cases where the fatty degeneration was most extreme, but the most striking pictures were obtained where the liver was least altered.

FIG. 1.—Liver cells, with necrotic masses, and small masses between and in the liver cells.

"In a few instances liver cells were found which only differed from the normal in being more coarsely granular, the granules staining with eosin but not so distinctly as the eosin staining bodies, and the nucleus stained more faintly blue than the nuclei of the surrounding liver cells. In most cases these bodies were without any nucleus; in others, a nucleus was present. This always was at the periphery, and generally took the long irregular form of the nucleus of a wandering leucocyte. Polynuclear leucocytes were numerous in all the livers examined. In some cases there were well defined groups of them in the capillaries and in the liver beam-work between, and, as it seemed, often in the red stained bodies. In several specimens there were hemorrhages in the liver, large areas being occupied by red blood corpuscles, between which the red bodies were often seen. This peculiar condition of the liver is possibly made more clear by staining the sections deeply with picric acid. In sections so treated, these bodies stain an intense bright yellow with the picric acid. Concerning the nature of these bodies there can be little question. When first seen it was thought that they were probably some form of lower organisms, possibly amebæ, but a more extended study showed that this could not be so. Bodies in all respects similar to them were found in rapidly advancing cases of cirrhosis of the liver, in phosphorus poisoning, and in other cases of rapid fatty degeneration, but they are particularly found in cases of acute yellow atrophy of the liver. Areas were found in sections from this which were very similar to the advanced cases of yellow fever liver. It must be considered that in yellow

low fever, along with the fatty degeneration, there is a necrosis of the liver cells, which sometimes affects only portions of the cells; at others the entire cell. Almost every change leading up to the formation of these bodies could be seen. The exact relation of the fatty degeneration to the necrosis could not be determined. The necrotic masses were found both in intact liver cells and in those which had undergone fatty degeneration. In the latter cases it seemed probable that the necrosis preceded, or at least accompanied, the degeneration. If it only represented a necrosis of the small remnant of cell protoplasm between the fat drops it is difficult to see how so large a body could be formed from this. When the necrotic masses were found in the liver cells they were nearly always at the periphery of the cell next to the capillary.

"Although these necrotic masses were generally found in the beam-work of liver cells, careful examination showed them frequently to be in the hepatic veins and in the capillaries. It would have been interesting to have examined sections of the lungs to determine what part they might play in the formation of emboli."

Figure 1 is a reproduction of one of the figures illustrating my report, and is made from a drawing by Dr. Councilman. For additional illustrations I refer to Figures 10, 11, 12, 13, 14 and 16, all of which are reproductions of Dr. Councilman's drawings.

(GEO. M. STERNBERG, M.D., LL.D.,

Surgeon General, U. S. Army.

ASSOCIATION NEWS.

Transportation Rates.—The following has been received from the Committee on Transportation appointed by the AMERICAN MEDICAL ASSOCIATION at Philadelphia, Pa.:

PITTSBURG, PA., April 25, 1898.

To the Editor:—We have assurance that other railroads east will follow the liberal action of the Western Passenger Association, and also give to the members of the AMERICAN MEDICAL ASSOCIATION one way rate plus two dollars for round trip and thirty days limit with stop over privileges west of Missouri River, and for those who want to go farther west at reduced rates to visit points of interest, there will be a low rate round trip from Denver to visit Salt Lake City at about \$18.

Yours very sincerely,

W. H. DALY, Chairman.

Liston H. Montgomery, Secretary. William Pepper, N. C. Scott, C. M. Drake, H. O. Marcy, J. W. Graham, J. D. Griffiths, Austin Flint, Committee.

The JOURNAL Special Train will go via the Burlington Route from Chicago.

Preliminary Announcement of the Committee of Arrangements.—The Committee of Arrangements announces that preparations for the coming meeting are well advanced. A large number of prominent men have signified their intention to be present and read papers, and an excellent scientific program is assured. The indications all point to a large and successful meeting.

Convenient and ample accommodations have been secured for the General Sessions, Section work, Registration and Exhibits.

The entertainment of members and their families is being planned on an elaborate scale, and the Committee promises all who come a most enjoyable time.

Denver is an interesting city, and the State offers many and varied attractions to visitors.

Local excursions are being arranged to take place after the meeting that all may have ample opportunity of visiting various points of interest in the State and seeing the best scenery of the Rocky Mountains.

The following is a list of the principal hotels of Denver with the rates agreed upon for the meeting:

The Brown Palace Hotel, 17th Street and Broadway. Take 17th Street (red) car to Hotel. European plan, \$1.50 per day and upward. American plan, \$3.00 to \$5.00 per day and upward. These regular rates will apply during the meeting for

available rooms if no reservation has been made. For reservations and rooms to be occupied by one person only, application must be made to Hotel for rates.

The Windsor Hotel, 18th and Larimer Streets. Take 17th Street car to Larimer Street. American plan, \$2.00 per day; room with bath, \$2.50 per day.

The Albany, 17th and Stout Streets. Take 17th Street (red) car to Hotel. American plan, \$2.00 to \$3.50 per day.

The Markham Hotel, 17th and Lawrence Streets. Take 17th Street car to Hotel. European plan, \$1.00 per day and upward.

All reservations at the Albany and Markham must be for the full term of the Meeting, and be paid for whether occupied or not unless canceled ten days in advance. They reserve the right to place persons occupying a room alone in a single room.

The New St. James Hotel, Curtis near 16th Street. Take 17th Street (blue) car to Hotel. American plan, \$2.00 to \$3.50 per day.

L'Imperiale, 14th Street and Court Place. Take Colfax Avenue car to Court Place. American plan, \$2.00 to \$3.00 per day.

Metropole Hotel, Broadway near 17th Street. Take 17th Street (red) car to Broadway. European plan, \$1.00 to \$2.00 per day. \$1.00 rooms, \$1.50 if occupied by two persons. No reservations made.

The Oxford Hotel, 17th and Wazee Streets. Two blocks above depot. European plan, \$1.00 to \$3.00 per day. An extra charge for two persons in one room.

The American House, 16th and Blake Streets. Take 16th Street car to Blake Street. American plan, \$2.00 per day.

The above hotels make no extra charge for reservations or for persons occupying a room alone except as stated.

The Hotel Broadway, Cheyenne Street and Broadway. Take Colfax Avenue car to Cheyenne Street. American plan, \$1.25 to \$1.50 per day.

The Vallejo, 1420 Logan Avenue. Take Colfax Avenue car to Logan Avenue. American plan, \$2.00 per day and upward.

The Devonshire, 14th and Logan Avenues. Take Colfax Avenue car to Logan Avenue. American plan, \$1.50 per day and upward.

The Albert, 17th and Welton Streets. Take 17th Street (red) car to hotel. European plan, \$1.00 to \$1.50 per day.

The Aldine, 1013 Seventeenth Avenue. Take 17th Street (red) car to hotel. American plan, \$1.25 per day.

The Richelieu, 1727 Tremont Street. Take 17th Street (red) car to Tremont Street. European plan, \$0.50 to \$1.00 per day.

The Earl, 1430 Tremont Street. Take Colfax Avenue car to Tremont Street. American plan, \$1.50 to \$2.00 per day.

Glenarm Hotel, Glenarm and 15th Streets. Take Colfax Avenue car to hotel. European plan, \$1.00 per day and upward.

The Bonaventure, 18th and Glenarm Streets. Take 17th Street (red) car to Glenarm Street. European plan, \$0.50 to \$1.50 per day.

The Drexel, 17th and Glenarm Streets. Take 17th Street (red) car to hotel. European plan, .75 to \$1.50 per day.

These hotels make small extra charges for two persons occupying same room. No charge for reservation.

Applications for rooms should be made to the hotels direct. For special information apply to ROBERT LEVY, M.D., Chairman Sub-Committee on Hotels, California Building, Denver, Col.

J. W. GRAHAM, M.D., Chairman.

W. A. JAYNE, M.D., Secretary.

Section on Laryngology and Otology.—B. Alexander Randall, Philadelphia, chairman; S. E. Solly, Colorado Springs, Col., secretary. A partial list of papers to be presented in this Section is as follows:

Adenoid Growths in Relation to Deaf Mutism, by A. C. Gatchel, Worcester, Mass.

A Penetrated Tube for Endolaryngeal Operation, by Thomas Hubbard, Toledo, Ohio.

Adenoid Vegetations of the Nasopharynx, by John O. McReynolds, Dallas, Texas.

The Bacillus Aerophilus in Chronic Suppurative Otitis Media, by Lewis S. Somers, Philadelphia.

An Improved Spray Apparatus, by Vard H. Hulén, Galveston, Texas.

Diseases of the Ear in Colorado, by P. F. Gildea, Colorado Springs, Colo.

The Diseases of the Base of the Tongue and Their Treatment, by Robert C. Myles, New York City.

The Faucial Tonsil, Its Relation to the Ordinary Diseases of the Nose and Throat, by G. B. Sweeny, Pittsburg, Pa.

On Phonation, by E. Cutter, New York City.

On the Histopathology of Hypertrophic Rhinitis in Children, by J. L. Goodale, Boston, Mass.

Tubercular Laryngitis, by F. E. Waxham, Denver, Colo.

The Tonsils as Portals of Systemic Infection, by Norval H. Pierce, Chicago.

Twenty-nine Successful Tracheotomies for Foreign Bodies in the Air Passages, with Remarks, by F. Westmoreland, Atlanta, Ga.

The Presence of Polypi and Granulations in Suppurative Diseases of the Ear Not an Unfavorable Indication, by Louis J. Lautenbach, Philadelphia, Pa.

Paper to be announced, by Francis M. Chisolm, Baltimore, Md.

Empyema of Maxillary Sinus, by J. A. Stucky, Lexington, Ky.

Tubercular Laryngitis, by S. E. Solly, Colorado Springs, Colo.

Medical Societies Entitled to Representation in the American Medical Association.—The following additions to the list published in the JOURNAL of April 16, page 929, should be noted: Pennsylvania, the Lawrence County and the Potter County Societies; Minnesota, the Winona County Society; Iowa, the Austin Flint Medical Society.

SOCIETY NEWS.

American Surgical Association.—The thirty-ninth annual meeting of the American Surgical Association was held at New Orleans, April 19, 20 and 21. The proceedings of this session will appear in the JOURNAL in an early issue.

The Omaha Medical Society, at its recent annual meeting, elected officers as follows: Richard C. Mann, President; Eleanor S. Dailey, first vice-president; E. W. Lee, second vice-president; J. M. Aikin, secretary; W. R. Lavender, treasurer; D. C. Bryant, B. L. Davis and C. C. Allison, censors; W. O. Bridges, Louis Swoboda and H. B. Wilson, committee on program. The Society has eighty members, meets twice each month and is doing much good work, local and State. Members of the regular profession, while in Omaha, en route to or from the National Association, in attendance at the Nebraska State Society meetings, in visiting the Transmississippi Exposition, will be cordially received by the local members, if they will make their presence known.

South Carolina Medical Association.—At the forty eighth annual session of the South Carolina Medical Association, held at Harris Lithia Springs recently, the following officers were elected: T. T. Earle, Greenville, president; G. R. Dean, Spartanburg, first vice president; W. G. Houseal, Newberry, second vice-president; E. F. Darby, Lynchburg, third vice president; E. F. Parker, Charleston, corresponding secretary; T. P. Whaley, Charleston, recording secretary; B. D. Baker, Charleston, treasurer. Drs. Robert Wilson of Charleston and G. R. Deau of Spartanburg were elected to fill the vacancies on the State Board of Health occasioned by the deaths of Drs. Bratton and Taber.

The German Congress of Balneology was held at Vienna in March, Liebreich of Berlin presiding. Kisch urged the necessity of thoroughly equipped laboratories at every watering place, for chemic, analytic and metabolic tests of the waters and examination of patients to individualize treatment. Römpler confirmed the significance of heredity and the infrequency of direct contagion in tuberculosis, mentioning that no case of tuberculosis had occurred among the 263 nurses in the Magdeburg hospitals during the last seventeen and one-half years, nor in his own personnel of 23, some of whom had been

in his establishment twenty-three years. Kobert exhibited a new bottle that can be filled without leaving an air space, a great improvement in examining mineral waters, especially those containing iron, as the water does not become turbid in it. Strasser discussed vegetable diet cures, remarking that the lemon cure for gout is now exploded. He observed that the benefits of a vegetable diet in chlorosis are mainly due to the change, as the same favorable effects are obtained with a return to the usual diet. Glax of Abbazia reported the results of twenty-five years study to the effect of balneotherapeutics on the diuresis. He stated that in individuals whose vasomotor system reacts to the slight stimulation of drinking cold water, this will promote diuresis, but not in persons with fever or disturbed circulation. The diuretic effect of cold effervescent waters is still more pronounced, but it is not sufficient to cause the absorption of the exudates in the pleura or pericardium, or of cardiac or renal hydrops. This can only be accomplished by limiting the amount of water ingested and substituting mineral water. This causes a surplus of salt in the blood and dries the tissues, which starts the process of absorption and diminishes the secretions in profuse bronchial catarrh. Some extensive tests demonstrated that with a decrease in moisture of the air from 100 to 71 per cent., the urine decreased from 90.5 to 70.7 per cent. of the fluids ingested. Speaking of distilled water as a beverage, Liebreich asserted that it is a powerful poison, its use liable to be followed by diseases, while the addition of a little salt removes this toxic property. M. Benedikt referred to the fully proven but still unexplained fact of the varying effects of different combinations of waters, urging in conclusion that water-cure physicians should report their failures as well as their successes: "science frequently benefits as much from the former as the latter." R. Buxbaum traced the etiology of certain cases of chlorosis and anemia to a lack of peristaltic action in the bowels, which is necessary for the maintenance of the circulation and pointed out the cure in restoring tone to the bowels. Loebel discussed menstruation in balneotherapeutics, observing that it was an indication to commence or continue the cure in some cases; in others a counterindication. But with proper care there was no justification for the general assumption that the baths were dangerous during the catamenial period. Winternitz extolled hydrotherapeutics in the treatment of round ulcer of the stomach, stating that not only the cardialgia but the pathogenetic phenomena were powerfully affected by it. The gastric pains are promptly relieved by cold sitz baths and by the application of a cold compress on the abdomen, under an airtight covering. To further the reaction a rubber tube wound in a flat spiral is laid on top of the compress, with a current of hot water kept flowing through it. He controls the gastric hemorrhage by introducing small pieces of ice into the rectum, which produce by reflex action an intense spasm of the vessels of the stomach, and arrests the hemorrhage much more effectively than any medication.

Wisconsin State Medical Society.—The provisional program of the fifty-second annual meeting, Milwaukee, May 4, 5 and 6, 1898, comprises the following papers:

Shall the Manufacturer Do Our Prescribing? by G. J. Haunheimer, Milwaukee.

Diet as a Therapeutic Agent, by Karl Kordeuat, Reedsburg.

Oxygen as a Therapeutic Agent, by W. B. Hill, Milwaukee.

The Treatment of Chlorosis, by Carl R. Feld, Watertown.

The Effects of Stimulating Narcotics, a Social Question, by Jno. Madden, Milwaukee.

Osteomyelitis, by H. A. Sifton, Milwaukee.

Intestinal Obstruction, by G. D. Ladd, Milwaukee.

Report of Case of Recurring Multiple Sarcoma Cured by Contracting Erysipelas, by P. O'Keef, Menominee, Mich.

The X ray in Fractures, by Ralph Chandler, Milwaukee.

Surgical Shock, by A. H. Levings, Milwaukee.

Fractures about the Elbow, by W. A. Batchelor, Milwaukee.

Some Remarks concerning Suitable Treatment Before, During and After Surgical Operations, by J. A. Jackson, Madison.

The General Practitioner and the Surgeon, by T. C. Malone, Milwaukee.

Supplementary Report on a Case of Traumatic Epilepsy Treated by Craniectomy, by H. Reineking, Sheboygan.

Some of My Experiences in Abdominal Surgery, by Jno. Specht, West Superior.

Tuberculosis of the Genito-urinary Organs, by J. R. McDill, Milwaukee.

Medical Treatment of Varicose Ulcers of the Leg, by G. A. Heidner, West Bend.

Cystic Kidney—with Exhibition of Specimen. Anomaly of the Vertebrae, with Specimen, by Dwight Mereness, Milwaukee.

Suppurative Synovitis of the Knee-joint, by D. B. Collins, Madison.

Report of Cases: *a*, Cicatricial Obstruction of the Gall-passages; *b*, Forty Gall-stones Removed from the Cystic Duct with Supseque Partial Stricture of the Duct; *c*, One Gall-stone of 2 cm. in Diameter Removed from the Duodenal End of the Common Duct; *d*, Two Hundred and Eighty Gall-stones Removed from the Gall-bladder with Perforation of the Gall-bladder and Colon; *e*, Laceration of Middle Meningeal Artery with Exhibition of Specimen, by F. Shimonek, Milwaukee.

The Operative Treatment of Hemorrhoids, by L. P. A. Valentine, Western Union.

The Function of Pathologic Anatomy, by A. J. Burgess, Milwaukee.

Demonstration of Microscopic Specimens, by A. J. Patek, Milwaukee.

Advantages of the Weigert Staining Method in the Study of the Normal and Pathologic Anatomy of the Nervous System (with Demonstration), by H. Reineking, Sheboygan.

Pathology of the Endometrium, by G. A. Kletzsch, Milwaukee.

The Physiologic Action of Bacteria and their relation to the Maintenance of Life, by V. A. Gudex, Milwaukee.

Catgut in Abdominal Surgery, by E. Copeland, Milwaukee.

Immediate Repair of the Perineum, by G. V. Mears, Fond du Lac.

Metro endometritis, by W. E. Ground, West Superior.

Uterine Myofibromata, by C. W. Oviatt, Oshkosh.

The Value of Ligation *en masse* of the Broad Ligaments in Removal of Ovaries and Tubes, with Demonstration of Figure-of-eight Ligature, by F. Shimonek, Milwaukee.

Colpotomy, by A. J. Puls, Milwaukee.

The Structures involved in Perineorrhaphy, by F. B. Robinson, Chicago.

Hysterectomy—Clamp Method, by E. T. Fish, Milwaukee.

The Relation of So called Nervous Diseases to Mental Alienation, by W. B. Lyman, Mendota.

Paretic Dementia, by S. B. Buckmaster, Hudson.

Etiology, Prevalence and Treatment of Hysteria, by U. O. B. Wingate, Milwaukee.

Treatment of Hysteria, by Darwin R. Stockley, Lake Geneva.

The Circulation of the Nervous System, by Herman Gasser, Plattville.

A Case of Amyotrophic Lateral Sclerosis with Degeneration in Goll's Columns and in the Medulla Oblongata, by S. H. Friend, Milwaukee.

The Importance of Early Treatment in Insanity, by Moses J. White, Wauwatosa.

PUBLIC HEALTH.

Quarantine Convention.

Held at Atlanta, Ga., April 12, 1898.

The convention was called to order at 10 o'clock, A.M., by Mayor Collier. Rev. Dr. Landrum opened with prayer. Owing to the non-arrival of many delegates, the session adjourned until noon, after the appointment of a credential committee and a committee on permanent organization. The report of the Credential Committee was received at the noon session, allowing all health and sanitary officers present to vote, and allowing each State five votes.

The Organization Committee reported the following officers, who were unanimously elected: President, H. B. Horlbeck, Charleston, S. C.; vice-presidents, E. A. Waugh, Virginia; De Sausure Ford, Georgia; R. L. Harris, Florida; Rhett Goode, Alabama; Murray, Mississippi; J. J. Scott, Louisiana; secretary, J. F. Weissinger, Atlanta. On roll call the States of South Carolina, Virginia, Georgia, Florida, Alabama, Mississippi and Louisiana were found to be represented.

President Horlbeck took the chair and appointed the following Committee on Plans and Resolutions: Drs. Souchon of Louisiana, Waugh of Virginia, Alexander of Georgia, Horsey of Florida, Goode of Alabama, and Haralson of Mississippi.

Resolutions relative to the regulation of quarantines were then introduced by Dr. Horsey of Florida, by Dr. Carter, the representative of the United States Marine-Hospital Service, and by Dr. Haralson. The resolutions presented by Dr. Haralson were adopted at a Montgomery convention twelve years ago. All the resolutions were referred to the Resolutions Committee, with which Dr. Wilkinson and Dr. Carter were invited to sit. An invitation to attend the reception last night.

in honor of General Graham was read from the Capital City Club and duly received and acknowledged.

The convention then adjourned until 4 o'clock in the afternoon to await the report of the Resolutions Committee, which went into session at once to agree on a composite report from the resolutions introduced.

Before the chairman of the Resolutions Committee read his report the convention decided to make the regulations to be adopted applicable to yellow fever only, notwithstanding the fact several delegates tried to include smallpox. During this discussion, Dr. Barron, president of the Board of Health of Macon, attacked Dr. Alexander, president of the Board of Health of Atlanta, for taking the position Atlanta was immune from the disease. Dr. Alexander replied in convincing style, and satisfied his hearers that the history of the city has substantiated his position.

The following resolution, recommended by the Resolution Committee, was then unanimously adopted:

Resolved, That this convention approves the plan of having medical inspectors attached to those consulates where yellow fever and cholera are epidemic, with a view of securing for our protection definite information as to the exact sanitary condition and the presence or absence of contagious diseases in such consular district. And that congress be urged to make the necessary appropriations to carry the plan into effect.

The following resolution from the same source was also adopted:

Resolved, That this convention is of the opinion that it is a duty devolving on all nations to take measures to eradicate any plague centers from their territory, and that the existence of such plague centers is a menace to all other nations, and that our State Department be requested to take measures through proper diplomatic channels for the conveyance of this opinion to the governments deemed obnoxious to the opinion as herein expressed.

The convention then unanimously adopted the following regulations, section by section, for the government of disinfection and detention camps, or camps for the shipment of merchandise:

In case yellow fever should occur at any point of the Southern States, the most effective method to prevent shotgun quarantines and their disastrous effects upon commerce is to establish disinfecting and detention stations or camps on the lines of travel by rail or boat.

It is by practical actions that the people will be reassured and not by agreements and persuasions based on words, assurances or legislation. To show the people that all possible care is effectually taken to prevent yellow fever from reaching them is the best and only argument they should yield to.

1. Parties coming from localities infected with yellow fever should not be allowed to enter quarantining localities of the south Atlantic and Gulf States, unless they have had their persons, clothing, baggage, etc., disinfected, and unless they have remained at the station ten days after such thorough disinfection, and places holding communication with infected localities may themselves be held in quarantine.

2. These stations or camps will be erected by the United States Marine Hospital Service.

3. They will be operated by the United States Marine-Hospital Service.

4. The Marine-Hospital Service will also be requested at an immediate date to prepare at least four disinfecting plants, including four cylinders for furnishing steam disinfection.

5. Medical inspectors from interested States and localities will be admitted to the stations to witness that the regulations are thoroughly complied with.

9. The clothes and baggage will be disinfected by moist steam under pressure.

10. Articles not amenable to this treatment will be immersed in a solution of 1 to 1000 bichlorid of mercury for one hour; or they will be placed in the formaldehyde chamber, fed from a generator for one hour, drying them first and spreading them in the chamber.

11. All articles requiring to be subjected to moist steam shall remain in the steam chamber at a continuous temperature of from 212 to 220 degrees F. for thirty minutes.

12. The persons will then be placed in the department of the disinfected and shall be inspected daily.

14. Upon the appearance of any tendency to yellow fever or any symptoms whatever of yellow fever, they shall at once be placed in a suitable isolated locality.

15. If they develop a case they shall be placed in the hospital of the station.

16. The persons will remain at the station ten days.

17. Persons thus detained will be given a certificate to the effect that disinfection has been practiced and detention of ten days enforced, signed by the resident officer of the United States Marine-Hospital Service.

18. Well authenticated immunes will not be detained, but will be disinfected.

19. Then the persons should be received everywhere and by everybody as being incapable of conveying infection.

20. Articles should not be shipped from dwellings, nor from places contiguous to dwellings, without being disinfected.

21. Class 1.—The following articles should be admitted without disinfection or restrictions of any sort: All new and dry material, unpacked, such as lumber, machinery, new brick, new tiling, bar and sheet iron, tin, steel, agricultural implements—no part of which is textile; iron, ties, stoves, saddlery not upholstered, wagons, new trunks, hardware without packing, lime, ice and salt in bulk, tar, turpentine, rosin, stone, gravel, coal, coke, cement, grain in car loads and cooperage, oysters and fish packed in ice.

22. Fruits, sound, when taken directly and in good condition from clean vessels and transferred at wharves not infected and in good sanitary condition immediately to the disinfected cars for shipment require no disinfection; freight taken directly from clean vessels, inspected and in good sanitary condition requires no disinfection.

23. Live stock and poultry also.

24. All disinfected cars to be placarded and way bills certified to by proper sanitary officers.

25. Class 2.—The following articles will require only superficial disinfection, that is, outside of container, by formaldehyde gas fed from generator: All goods in original wooden or metal packages, not broken or packed in an infected locality. This class embraces boots and shoes in original packages, cotton, dry goods in original cases, leather goods, saddlery and saddlery hardware, drugs and chemicals in solid cases or packages, rubber and oiled clothing, sugar in boxes or barrels, rice in barrels, canned fruits, vegetables, meat and oysters, also condensed milk in solid unbroken boxes, stone, iron or tinware, tobacco and cigars, wines and liquors, cheese in original boxes, flour, grits and meal in barrels, woodenware, butter, tea in caddies, candles in boxes, lard, pork, bacon, oils and paints in tin cans or barrels, soap in boxes, axle grease, iron roofing, saddle-trees, raisins, matches, salted fish, potatoes, onions and apples, molasses.

26. Goods other than textile packed in textile material, not broken in infected locality and kept perfectly dry, do not require disinfection, except the container. This includes coffee, grain and spices in sacks, as also cured hams in canvas.

27. Class 3.—Articles not in the above classes, if they have been exposed to infection, will be disinfected before they are shipped; the efficiency of said disinfection shall be certified to by the proper health authorities. This refers to all merchandise not manufactured in infected locality, but kept in stock for distribution, which has not been exposed to any infection and may be safely shipped without being fumigated.

28. When it has been exposed to infection, then it should be fumigated to be made harmless.

29. When desired, all goods of this character can be made to undergo a treatment of fumigation and disinfection before being certified to by the proper health authorities.

30. Articles mentioned above that can be packed in excelsior, in perforated container, rendering the excelsior and contents capable of disinfection, will be disinfected and passed.

31. Class 4.—During the prevalence of yellow fever in any city, town or locality, no bedding nor household effects from such city, town or locality shall be received for shipment to other points.

32. All certificates and all disinfections are subject to inspection and approval by authorized agents, who may be sent by the various health authorities.

MARINE HOSPITAL INSPECTION.

33. Each establishment packing and repacking will employ and pay a sanitary inspector appointed by the United States Marine Hospital Service.

34. At the hour of arrival of the workmen at the establishment he will see that they are all gathered in the same place and the doors barred and remain so; also the doors of the rooms where they are at work.

35. They will disinfect the exposed parts of their bodies.

36. They will remove all of their clothing down to the skin.

37. They will don disinfected clothes, which will be clean and left by them the day before and pass through the formaldehyde chamber as above.

38. The sanitary inspector must also be disinfected in like manner as the workmen.

39. They will then only be permitted to open original packages in a previously disinfected room and distribute them and form other packages.

40. When these packages are completed and closed they will be stamped by the sanitary inspector as inspected and safe.

41. During the work the sanitary inspector will watch the work all the time.

42. After the work the workmen will remove their clothing and don their ordinary clothes, which, during the working hours, have been passed through the formaldehyde chamber.

43. The same regulations apply to operators in factories which intend to ship their goods to non-infected localities.

44. In addition, such goods themselves must be disinfected.

45. A general supervisor, employed by the United States Marine-Hospital Service, will check the efficiency of the sanitary inspectors in stated sections or a number of establishments.

46. In case of disobedience of any of the regulations the sanitary inspector will refuse to stamp the packages.

47. In packing goods into original packages only such packing material must be used as has been disinfected within the previous twelve hours.

48. A medical or sanitary inspector from interested States or localities will always be admitted at once into the establishment to see if the regulations are carried out properly.

49. All freight in cars and the cars themselves, and all freight on or in boats and such part of the boats themselves shall in all cases be disinfected by the United States Marine-Hospital Service whenever and wherever that service may deem the same necessary.

FOR THE REGULATION OF THE DISEASE.

At the evening session the convention first adopted the report of the Resolutions Committee concerning the regulation of the disease, which was as follows:

REGULATIONS FOR YELLOW FEVER.

1. Localities infected with yellow fever and localities contiguous thereto, should be depopulated as rapidly as possible, so far as the same can safely be done.

Persons from non-infected localities, and who have not been exposed to infection being allowed to leave without detention and in leaving such place shall be presented with health certificates by the legally constituted health authorities of the place.

1. If an inspection shows that the disease be certainly confined to a few houses, and all persons who have been exposed to possible infection are known, and these houses and people be isolated under observation, the remainder of the town need not be quarantined; should either of these conditions fail, the town shall be quarantined.

2. When practicable, the patient shall be removed to hospital or other quarters little liable to infection, and so situated as to involve a minimum of danger, if infected.

3. If the patient can not be removed, all possible precautions must be taken to prevent contamination of his premises.

4. Those certainly immune to yellow fever may be given free pratique after disinfection of effects.

5. Non-immunes may be permitted to go to places incapable of infection, to remain there during the period of incubation, requiring disinfection of baggage, unless certain that it will remain in such territory.

6. Non-immunes not going to such places, shall, if practicable, be isolated under observation in non-infected quarters, so situated that if fever develops among them there shall be as little danger as possible of conveying infection; their effects being disinfected upon isolation.

7. Such persons as are isolated under observation on account of exposure to yellow fever, shall be so isolated for a period of not less than ten days from the last possible time of exposure to infection. They shall be inspected—twice daily is advised.

8. Premises occupied by, or having been occupied by, a case sick with yellow fever, shall be treated as infected, and be under sanitary control; and such neighboring premises as are close enough for their inmates to receive infection from the above shall also with their inmates be under sanitary control.

9. These premises shall be strictly guarded, and no communication allowed with those outside except under such rules and supervision as will prevent the conveyance of the disease.

10. All possible precautions shall be taken to prevent exposure of the guards and other attendants to infection. If possible, they shall be immune. They shall be under proper supervision.

11. On the recovery, removal or death of a case of yellow fever, the premises shall be immediately disinfected, and such neighboring premises as from proximity are presumably infected are also to be disinfected.

12. Coincidentally with the foregoing measures a house to house inspection should be made of the whole community to determine whether other cases exist.

13. In the case of the death of a patient the body shall be disposed of under such sanitary precautions as will prevent the conveyance of infection.

WHEN QUARANTINE IS NECESSARY.

1. If the inspection of a town in which yellow fever exists does not show that all foci of infection, possible fomites and persons liable to develop the disease, are under observation ("in quarantine"), or if cases occur which can not be traced to any known focus, such town shall be subject to quarantine.

2. Those who have been exposed or who come from infected localities shall be required to undergo, in the camp of probation or other designated place, a period of detention and observation of ten days from date of last exposure, before being permitted to proceed to a locality capable of being infected, their clothing and other effects capable of conveying infection being disinfected upon entrance to place of detention. For persons known to be immune to yellow fever, detention is not required, merely the disinfection of their baggage and clothing.

3. Persons who have been exposed may be permitted to proceed, under proper sanitary supervision while passing through infectable territory, without detention, to localities incapable of becoming infected, and whose authorities are willing to receive them, to remain there ten days. The baggage of such persons shall be disinfected unless it is certain they will not return into infectable territory. This exemption from disinfection shall not apply to baggage from an infected house for any point, or to baggage to points which object to receiving it undisinfected.

Note—On account of the extreme difficulty of the health officer determining the ultimate destination of passengers bound for Atlanta, Charlotte, Nashville and similar distributing points or passengers south, the baggage of such passengers should be disinfected.

4. An adjacent town which is in direct communication with an infected town must be considered as being neutral territory, and therefore under quarantine, as shall also be such territory as from its proximity or relations to an infected town can not be pronounced certainly clean.

METHODS OF DISINFECTION.

The following methods of disinfection are considered efficient:

FOR YELLOW FEVER.

1. Apartments or dwellings infected with yellow fever to be disinfected by one or more of the following methods:

(a) By a thorough washing of all surfaces of apartments with an efficient germicidal solution.

(b) By sulphur dioxide for twenty-four hours' exposure, four pounds of sulphur for each 1000 cubic feet, plus due allowance made for waste.

(c) By formaldehyde gas in not less than a 4 per cent per volume strength, and not less than six hours' exposure.

Note—One liter of 40 per cent. solution of formaldehyde gas will evolve about 1425 liters (50.1 cubic feet) of gas at 20 degrees C. (68 degrees F.).

2. (Grounds, out buildings, etc., deemed to be infected, to be disinfected with a strong solution of crude carbolic acid (carbolic acid, crude, 2 parts; sulphuric acid, 1 part; water, 25 parts) or an acid solution of bichlorid of mercury (1500); disinfection of ground preferably by fire.

3. Bedding, wearing apparel, carpets, upholstered furniture and the like to be disinfected by one or more of the following methods:

(a) By steam at a temperature of 100 to 102 degrees C.: thirty minutes' exposure.

(b) by boiling, all parts of the articles to be submerged.

(c) By saturation in an efficient germicidal solution.

(d) By thoroughly wetting the surfaces of articles with a 40 per cent. aqueous solution of formaldehyde, and placing them in a closed space for not less than twelve hours.

(e) Where surface disinfection is required formaldehyde gas of not less than a 4 per cent. per volume strength and not less than six hours' exposure, or by sulphur dioxide for not less than twenty-four hours.

4. The dejecta from cases of yellow fever to be disinfected by an efficient germicidal solution.

Mails to be disinfected by one of the following methods:

(a) By formaldehyde.

(b) By sulphur dioxide.

(c) By steam.

(Newspapers must be made up in such packages as shall be penetrable to the disinfectant used.)

MISCELLANEOUS.

Articles injured by steam, such as rubber, leather and containers, to which disinfection by steam is inapplicable, to be disinfected:

(a) By thoroughly wetting all surfaces with an efficient germicidal solution, the articles being allowed to dry.

(b) By exposure to sulphur dioxide.

(c) By exposure to formaldehyde gas.

The application of gaseous disinfection to these articles should be made in a closed space, air-tight or as nearly so as possible.

The following are considered efficient germicidal solutions:

1. Bichlorid of mercury, acid, 1-1000.
2. Carbolic acid, pure, 5 per cent. solution.
3. Trikresol, 2 per cent. solution.
4. Solution of formaldehyde, 1-500 (which is 2 parts of a 40 per cent. solution of formaldehyde to 25 parts of water).
5. Solutions of hypochlorite of calcium (chlorid of lime).

FOR THE RAILROAD TRAFFIC.

The following regulations from the Committee as to the government of railroad traffic in infected towns was then adopted

TRAINS THROUGH INFECTED TOWNS.

1. A passenger train to infectible locality shall not stop in an infected town, nor shall the windows or doors be allowed to be open therein: and no communication shall be allowed between the passengers or train crew and the town.

2. Freight traffic through such a town should be without stopping.

In cases where stopping in town is absolutely necessary for freight traffic and also when the town is large, and the infection general, a special crew shall take the train through the town. The relay stations where these changes are made, shall be under sanitary supervision.

3. Sanitary inspectors should also be stationed in town.

Through traffic, i.e., to points incapable of receiving yellow fever infection, to be designated hereafter as "points north."

1. Freight.—Freight in sealed cars can go without hindrance through to destination.

2. Empties.—Empties must not stay in an infected town or be parked in an infected locality. Flat cars must be swept clean.

Boxcars made mechanically clean and dry and sent open to the relay station where they are to be inspected for tramps. From the relay station they should be sent on under seal.

All fruit cars to be disinfected.

3. Mail.—Through mail not distributed south needs no quarantine restrictions save disinfection of bags.

Parcels except mercantile sample packages to be barred.

4. Passenger.—Traffic to points north can be allowed by preventing all chance of such passengers conveying infection en route, either by themselves leaving the train en route or by returning to points south or by fomites: mainly their clothing.

This traffic must be on special cars reserved for these passengers, and preferably on a special train. A sanitary inspector must accompany them through the quarantined territory, under whose absolute sanitary charge the train is.

The coaches which carry these passengers must be disinfected before they return south.

THE DUTIES OF INSPECTORS.

5. Train inspectors must be properly relayed and those running from the infected town should be immune. If they sleep in clean territory they must be immune.

6. Cars should be removed from an infected locality as soon as empty. If not, they should be disinfected where they have been. They should be sent with windows and doors open and carefully inspected at the relays for tramps.

Mail—Letter mail needs no disinfection; newspapers must be disinfected; parcel mail is prohibited altogether.

All train crews from an infected town must be changed and not be allowed to have direct communication with certainly clean territory. This should be done at a non infected place as isolated as possible, a siding rather than a station, and certainly not in a town.

Every man, mail agent, expressman and train butcher, must make this relay, unless we know that he is going north not to return to points south, in which case he is like a through passenger. Pullman crew to be relayed.

None of the merchandise of the train butcher, unless disinfected newspapers be excepted, must pass the relay. No possible fomites must pass the relay to the crew bound north and as little communication as possible—none save such as is necessary for the run of the train is allowed. The relay must be under the supervision of a sanitary officer or officers (two are generally required) whose position is one of great responsibility. At these stations a very careful search for tramps must be instituted.

The camps from the north and south crews should be at a considerable distance from each other, and the run of trains should be arranged so as to have the crews in camp as little as possible. For passenger trains there need be no delay; for freight trains generally there must be and their crews go in camp.

Occasions may arise where it is necessary to guard the southern relay camp by a number of guards, as if it were a camp of detention. It must never be allowed to become infected. If it does the camp must be moved.

Laundry for Pullman cars not to be done in infected places.

Steamboat communication can be carried on:

1. By relays like railroad trains.
2. By supervision of the landings of freight and loading of same, so as to prevent communication between the people ashore and the boat.

It is confessedly difficult, but possible.

FORM OF HEALTH CERTIFICATE.

The convention then adopted the following form of health certificate to be used in the Southern States during the yellow fever epidemics:

Office of Board of Health of _____.

Health Officer _____
To Whom it may Concern:

This is to certify that Mr. _____ has given satisfactory evidence to me that he has been in _____ not less than ten days, and, to the best of my knowledge and belief he has not been exposed to the infection of fellow fever, and has not been in any infected or suspected locality for ten days.

Descript on: Age _____ years. Weight _____ pounds. Height _____.
Complexion _____. Hair _____. Eyes _____.

Signature: _____

Health Officer.

When deemed necessary affidavit shall be required by the health officer.

The certificate shall be issued without fee.

STATES GOVERNED BY REGULATIONS.

A resolution was adopted instructing the secretary to send copies of the convention proceedings to the governors of North Carolina, South Carolina, Georgia, Florida, Alabama, Mississippi, Louisiana, Texas, Tennessee and Arkansas, with instructions that they communicate the same to their respective health officers.

The convention decided to forward a copy of the proceedings, which will be published in attractive form, to every member of Congress. Votes of thanks were tendered to the officers of the convention, to Manager Scoville of the Kimball House, to the *The Atlanta Constitution* and *The Atlanta Journal*, and to the railroads for courtesies extended the delegates. The chairman was instructed to appoint, at his leisure, a committee of three, looking to the organization of a permanent Southern Health Association.

The following delegates were present:

Virginia—Dr. E. A. Waugh, Lynchburg; Dr. J. Jett McCormick, Norfolk.

South Carolina—Dr. H. B. Horlbeck, Charleston.

Georgia—C. A. Collier, Atlanta; Dr. J. F. Alexander, Atlanta; Dr. C. F. Benson, Atlanta; Dr. James B. Baird, Atlanta; Dr. Louis H. Jones, Atlanta; Dr. DeSaussure Ford, Augusta; Dr. D. C. Ticknor, Columbus; Dr. R. B. Barron, Macon; Hon. P. W. Meldrim, Savannah; Dr. Ed. Brobston, Brunswick.

Florida—Dr. J. L. Horsey, Fernandina; Dr. R. L. Harris, Orlando.

Alabama—Dr. Glenn Andrews, Montgomery; Dr. J. W. Barclay, Birmingham; Dr. R. D. Murray, Mobile; Dr. Edward A. Neil, Selma.

Mississippi—Dr. H. H. Haralson, Biloxi; Dr. C. M. Murry, Ripley.

Louisiana—Dr. C. P. Wilkinson, New Orleans; Dr. Edmond Souchon, New Orleans; Dr. Quitman Kohnke, New Orleans; Dr. J. J. Scott, Shreveport; H. R. Carter, New Orleans.

Missouri—Dr. Sam Ayers, Kansas City.

United States Marine-Hospital Service—Dr. H. R. Carter, R. D. Murray.

Railroads—Joseph M. Brown, Atlanta, Nashville, Chattanooga and St. Louis railroad and Western and Atlantic; J. C. Smith, Atlanta and West Point, Atlanta; J. H. Sullivan, Kansas City, Memphis and Birmingham; D. D. Curran, New Orleans and Northeastern railroad; J. S. B. Thompson, Southern railway. Atlanta—*Atlanta Constitution*.

How Long will Diphtheria Serum Retain Its Efficiency? This question is discussed by P. Aaser, the editor, in the *Tidskrift for den Norske Lægeforening*, March 15, who decides after comprehensive research, that as long as the serum remains clear, even if it is several years old, its efficiency is unimpaired. A slight sediment does not show deterioration, although care

must be taken not to inject it. He also asserts that freezing and then thawing do not affect its action, and suggests that frozen serum may possibly keep indefinitely. The serum is not affected by heat unless sufficient to coagulate it, or of long duration.

Tuberculosis in the French and German Armies.—The dismissals and deaths on account of tuberculosis in the French army have risen from 5.48 per cent. in 1888 to 9.48 per cent. in 1895. The increased mortality is generally ascribed to the grip, which seems to be recurring every year with increasing malignancy. The corresponding German statistics are much less somber, as the general mortality from 1886 to 1891 was only 3 per cent. and it has been about the same since, in which the mortality from tuberculosis is less than 1 per cent.—*Deu. Med. Woch.*, March 10.

"White Death" is the name given by Professor Spatzuzzi of Naples, to the consequences of the condition of the poor in that city; death from slow starvation, exhaustion, poverty, degeneration, with anemia, and emaciation. Professor Colajanni asserts that these lamentable conditions are growing worse; the poor get no air, no oxygen, nor even light; but live pell-mell in lodgings that have nothing human about them, but resemble more the dens of wild beasts. The number of inhabitants to a square kilometer is said to be 196 at London; 265 at Paris; 280 at Rome; while it is 939 at Naples, and in the Pendino district it is 1254. The city is supplied with spring water, and typhoid fever has almost completely disappeared, but the general mortality is still 30 to 33 per thousand.—*Journ. de Méd. de Paris*, X 5.

Freire's *Cryptococcus Xanthogenicus*.—The committee appointed by the government of Brazil, at the request of Professor Freire, have rendered their report, although they do not consider it complete, owing to the lack of a sufficient number of cases of yellow fever, human and experimental, for more thorough research. They describe the micrococcus as a small spheric cell, extremely refragent, translucent, containing one or more nuclei and cilia, staining readily with anilin stains, not discolored with the Gram, rapidly motile, and measuring nine tenths to one and two-tenths of a thousandth of a millimeter. No micrococcus has been described in literature that can be confounded with it, not even Rosenbach's pyogenes aureus. They therefore consider it a new species, investigated by Professor Freire as the causative agent of yellow fever. Guinea pigs, rabbits and young dogs inoculated with it presented symptoms and anatomic pathologic lesions "very similar to those of yellow fever."—*O Brazil Médico*, March 1.

Insanitary Conditions in a Turkish Village.—Mr. G. W. Steevens, who was the war correspondent of the *Daily Mail*, London, and an aide on the staff of Gen. Edhem Pasha, in the late Greco-Turkish war, has written a book, entitled "With the Conquering Turk," that will attract considerable attention. He gives the following picture of the aboriginal state of a Turkish village in war time: "It was a jumble of huts, partly unmortared stone, partly mud bricks dried into stone and washed by the rain into mud again. The dirty little houses had dirty little courts before them enclosed in high stone or mud walls. Here and there squatted a soldier; here and there a beggar: here and there a black blot, which on nearer view became a Turkish woman in domino. The road that ran through this village was an open sewer; the horses splashed along it hoof deep in filth. In the middle of it dogs were gnawing at a dead donkey, one-half bones and the other half putrefaction. Now and again we had to scramble over heaps of dung as high as a man, and on the top of these played children, pretty, brown-skinned, limpid-eyed girls, with pig tails down their backs and trousers down to their bare feet. These were fat and ruddy enough for children. But the stink of that village was an abiding horror."

National Health Bureau.—The Committee on Legislation of the Trades League offered the following, which were adopted:

WHEREAS, There is at the present time no general system of sanitation and disinfection throughout the United States, guided and controlled by one general head and working in harmony with local and State Boards of Health; and

WHEREAS, The presence of an epidemic of contagious diseases in any part of the country without such general system of control breeds fear and panic from a lack of confidence in the ability of the local Board of Health to control the epidemic within a contracted radius of territory; and

WHEREAS, Localities within hundreds of miles of the infected district quarantine against it, and other places near it, thus resulting in enormous losses to commercial and transportation interests of the country at large; therefore, be it

Resolved, That the Trades League of Philadelphia, an organization of nearly two thousand business firms, earnestly recommends the establishment by the National Government of a commission of public health, to be known as the "National Commission of Public Health," which shall be a bureau in the Treasury Department, and the duties of which shall be to collect and disseminate information with regard to the prevalence of infectious diseases in this and other countries, to collect and publish vital statistics, to prepare rules and regulations for securing the best sanitary conditions of vessels from foreign ports and for preventing the introduction of infectious diseases into the United States and their spread from one State or Territory or the District of Columbia, and, in general, to make investigations, publish information and formulate rules with a view to the preservation of the public health.

Resolved, That the Legislative Committee of the Trades League shall give the subject their careful and prompt attention, with "power to act" as the importance of the subject may demand.—*Public Ledger*, Philadelphia, April 15.

NECROLOGY.

GEORGE W. LEONARD, M.D., born in Newburg, N. Y., in 1847, and a graduate of the University Medical College, died in New York city, April 16. He was a charter member of the Colonial Club, and was once the surgeon of the Seventy-first Regiment N. Y. State militia. A widow and a son are his survivors.

JAMES A. C. MCCOY, M.D., Tacoma, Wash. At the opening of the war he became assistant surgeon of the Forty-ninth Regiment Indiana Volunteers, and later a surgeon in the United States hospital at Mound City, Ill. At the close of the war he went to Indianapolis, where he engaged in practice, but left in 1879 for Washington, where he was appointed physician for the Puyallup Indian agency, which position he held until 1882.

ERASMUS R. GARROTT, M.D., Chicago, died April 19, aged 62 years. Dr. Garrott was born in Maryland, and was graduated from the University of Maryland in 1856. When the civil war broke out he joined a regiment of Colorado rangers as surgeon, afterward, in 1873, locating in Chicago, where in 1876 he became associated with the Health Department. During the smallpox epidemics of 1881, 1882 and 1894, his services were invaluable. At the time of his death he was Chief Medical Inspector of Chicago's Health Department.

ELISHA W. AIKEN, M.D., Boston, April 13, aged 70 years.—S. M. ANDERSON, M. D., Mattoon, Ill., April 19.—Major Henry McElderry, M.D., chief surgeon of the Department of the Missouri, April 17, at Hot Springs, Ark.—R. B. RAWSON, M.D., Woodland, Mich., April 18, aged 62 years.—ANDREW WALL, M.D., Cambridge, Ohio, April 17.—EDWARD D. WELLS, M.D., Westminster, Md., April 15, aged 48 years.

MISCELLANY.

The Physicians of Berlin Have Organized a Club to promote social intercourse among the members of the profession, afford a place to entertain visiting medical friends, etc. The project has been greeted with enthusiasm and over three hundred have signified their intention to join.

A Bengalese Proverb.—The Bengalese saying, "Do not wake up a sleeping physician," is supposed to have been based upon a feeling of consideration for the man of healing. But it also brings to mind that English adage about letting sleeping dogs lie; also that other older proverb, *Quia non movere*.

The Malaria Parasite.—The Surgeon-General of the Army, George M. Sternberg, M.D., contributes to *The Youth's Com-*

panion, for April 28, an article on "The Malarial Parasite." This brings to mind the fact that a few years ago, while stationed in Baltimore, he engaged in experimental researches in bacteriology at Johns Hopkins University, as a fellow, by courtesy of that institution.

Notice of Removal.—The *International Journal of Surgery* will remove May 1, 1898, to the Woodbridge Building, No. 100 William Street, New York.

New Publication.—The *Memphis Lancet* will begin publication July 1, 1898. It will be published on the first of each month, contain fifty-four pages of reading matter, and is designed to furnish the profession of the Mississippi Valley with a progressive and representative journal.

Heredity in the Color of the Eyes.—E. Storen states that in over 74 per cent. of several hundred persons he has examined, the color of the eyes can be traced to inheritance from the grandparent of the same sex on the side of the parent of the opposite sex: boys from their mother's father and girls from their father's mother. — *Tidsskrift f. d. Norske Lægeforening*, xviii, 1.

Immunity to Tetanus Conferred by Pneumococcus Vaccination.—G. Tizzoni announces that inoculation with pneumococcus vaccin not only protects rabbits against pneumococcus infection, but also against the smaller fatal doses of tetanus toxin. Tetanus vaccin also renders the animal more resistant to pneumococcus infection but does not save it from death at last. — *Gazzetta d. Osp. e d. Clin.*, March 6.

Removal Notice.—The well known house of Victor Koechl & Co., importers of medicinal preparations, such as antipyrin, lanolin, Behring's antitoxin, argonin, orthoform, etc., etc., announce their removal from No. 79 Murray St. to the new and modern six story building No. 122 Hudson St., corner of N. Moore St. The necessity of obtaining larger and more commodious quarters and better shipping facilities is the reason for making this change.

Etiology of Congenital Dislocations and Curvatures.—Three writers recently have called attention to the probability that congenital dislocations and malformations of the limbs, are caused by an insufficient quantity of amniotic fluid, thus exposing the fetus to mechanical pressure from the walls of the uterus. Weissenburg in Russia; Hirsch, *Virchow's Arch.*, Vol. 148. No. 3, and A. Schanz in the *Ztschrift. f. Orth. Chir.*, Vol. 4.

The Antediluvian is Safe.—The antediluvian editor of the *Sanitarian*, who for years has been running a mendicant sheet, seems to have a great fear of an insane hospital. He is protected by his autiquity both from bodily harm or from a commitment warrant. Few judges are likely to commit an old man far advanced in his dotage, whatever may be his delusions and vagaries. He may sleep as sweetly or sourly as his ancient frame will permit. He is safe.

Cure of a Suppurating Osteo-periostitis with the Roentgen Ray.—A rebellious case of osteo-periostitis of the cubitus, that had lasted two years, completely cured by the application of the Roentgen ray, is reported in the *Revista portuguesa de Med. e Cir.*, 1897, No. 25. The remarkable effect of the ray was noticed accidentally as a radiograph of the part was being taken; the fistulas began to discharge copiously and contract, the region to swell, etc., and a daily twenty minute application soon healed the lesion. — *Presse Méd.*, January 22.

Chloroform Cholemia as a Complication of Celiotomy.—Chiarleoni reports two cases of severe icterus, extreme pruritus, prostration, somnolence and mental disturbances, pupils immovable and midriatic, one a midwife of 36, the other a young woman of 22. The symptoms appeared immediately after oöphorectomy for osteomalacia in the first case and laparotomy for a cyst in the broad ligament in the other, requiring respectively 25 and 50 grams of chloroform. The symptoms grew worse for six

days and then gradually retroceded, disappearing by the twelfth day. He is inclined to ascribe the complications to the action of the chloroform on the hepatic gland, as various investigators have noted the alterations produced in the liver and kidney by chloroform. — *Gazzetta degli Osp. e delle Clin.* March 20.

Aseptic Traumatic Fever.—Holmes states that this condition is due to the absorption of pyretogenetic substances formed from the products of the aseptic necrobiosis after traumatism (*vide JOURNAL*, xxix, p. 730), as Volkmann, Gangolphe and others have confirmed. Pillon has established that the white corpuscles secrete fever-producing substances, by centrifugalizing blood from a horse and injecting dogs with the cells in salt solution. The longer the interval since the isolation, the higher the temperature induced by the injection. He does not venture to say whether this substance is due to the fibrin ferment, the uric acid or the nuclein. — *Cbl. f. Chir.*, March 12.

Chronic Splenomegalic Infectious Icterus is an affection described by Professor Hayem in the *Presse Méd.*, of March 9, with reports of five observations. It is characterized by chronic icterus of indefinite duration, 19 years in one case, with transient paroxysmal attacks, moderate hypertrophy of the liver, pronounced tumefaction of the spleen with progressive sclerosis, digestive disturbances and more or less anemia. A microbe was discovered in the spleen in one case which killed mice in twenty-four hours, resembling the pneumococcus. He considers it probable that the microbial agent comes from the intestines and varies from one case to another. The treatment is symptomatic, addressed particularly to the digestive apparatus. All the cases were accompanied with parenchymatous gastritis, as usually with catarrhal icterus.

Alterations in the Shape of the Trachea.—Simmonds, prosector at the large hospital at Hamburg, has been making a study of casts of tracheas. He found numerous constrictions, dilations and angularities; scoliosis was noted in one-fourth of all the cases. Constrictions produced by the pressure of aneurysms, tumors and latent goiters were frequent, also a groove which he attributes to the pressure of the arteria anonyma. The walls were frequently found ossified and flattened in elderly persons, for which he suggests the descriptive name of "senile sabersheath trachea." Universal dilation was only noted in one case, probably congenital, but partial ectasia was common, almost invariably in the middle section of the rear wall, in elderly persons, accompanied with atrophy of the wall. His report in the *Mitth. a. d. Hamb. St. k. Anst.* is illustrated. — *Cbl. f. Chir.*, March 12.

The Excess of Ammonia Frequently Noted in the Urine of Infants, is caused primarily, as Czerny has recently demonstrated, by a surplus of acids in the blood. The administration of an alkali would suppress the excess of ammonia. Further research proved that the excess of acids was derived from the fats. The increased acidity and excretion of ammonia may be produced by abnormal amounts of acids derived from the fats, with normal powers of oxidation, or, with diminished oxidation, by acids absorbed by the normal stomach. As we can not assume an unlimited ability on the part of the organism to elaborate ammonia to neutralize the acids, we can now understand better the injury from constant acid reaction. In determining the value of a food in calories, we must also take into account the acids that remain unoxidized. — *Wien. kl. Woch.*, March 31.

Diagnosis in Typhoid Fever.—Barber (*N. Y. Med. Jour.*, April 16) reports a series of tests showing the "Comparative Value of the Diazo Reaction and the Blood Serum Test in the Diagnosis of Typhoid Fever." The serum test proved the most reliable, appearing in every case but one, and appeared in no other disease. The diazo reaction was an advantage in that it appeared earlier in the disease in nearly twice the num-

ber of cases. In almost every case where the serum reaction appeared first the diazo reaction was present on the following day, while in many cases the serum reaction was absent for several days after the diazo reaction was found. He believes that Ehrlich's test is by far the better for the general practitioner, no expensive laboratory being required, while it is easily and quickly made, and with little experience the reaction can be detected in nearly every case. The diagnosis should always be confirmed by the presence of the serum reaction.

New Diagnostic Sign of Measles. In the *Medical Record*, April 9, Koplik describes in detail a phenomenon previously claimed by him to be a new diagnostic sign of measles. This sign is an eruption which appears on the mucous membrane of the cheeks and lips fully twenty-four hours, often forty-eight or seventy-two, before the eruption on the skin. It spreads and reaches its height just as the skin eruption has appeared and is spreading: it then fades. The eruption consists of small irregular spots of a bright red color; in the center of each spot is the interesting sign, seen only by strong daylight, a most minute bluish-white speck in the center of the reddish spot. They are not so large nor so deeply white as sprue and they are not seen on the hard or soft palate nor after the mouth has been washed. They always maintain their punctate character and do not coalesce. To be seen, it is necessary to evert the mucous membrane covering the lips and cheeks, either with the fingers or a spatula. "One can then see the infinitesimally minute bluish-white specks on a reddish punctate area in beginning measles, and on a more diffuse reddened background in advanced cases, which are absolutely pathognomonic of measles."

Hot Water Potations.—Every drug store which makes a specialty of mineral waters and such things now includes hot water among the refreshments offered to the public. Hot water would possibly be more appropriately included among the medicines, for it is improbable that anybody ever takes it from the same motives that lead a person to order ice cream soda. The relish with which the consumer of hot water gets rid of a cup, however, is quite as apparent as that of those who take more familiar beverages. The confirmed victims of the hot water habit have been known to order their tippie at a particular temperature and accept it only when assured by the thermometer just what the degree of heat is. These patrons are looked upon as more of a nuisance than the others, and the clerks who show patience with them have the satisfaction of knowing in many cases that they are not incurring the risk of loss for their employers. Most of the stores charge nothing for hot water. In others the price varies. Some establishments rank it along with vichy, seltzer and such things at 5 cents. But other places, evidently seeking to discourage the habit, ask ten cents a glass.—*N. Y. Sun.*

Connection Between the Thyroid Gland and Puberty.—E. Hertoghe ascribes a preponderant role to the thyroid gland in both physical and intellectual development, and also a specific action upon the morphologic formation of the genital organs in both sexes. It has long been noted that the thyroid gland develops parallel to the development of the genitalia, but he is convinced that the sexual development results from the thyroid hypertrophy and increased thyroid secretions. Arrested growth or infantilism is therefore due to imperfect development and activity of the thyroid gland, and complete myxedema is the extreme degree of thyroid degeneration. "Dysthyroidism" is principally characterized by arrested growth and absence of puberty, as in cretins. The degree of infantilism depends upon the amount of dysthyroidism, from simple obesity, rachitism, chondro-fetal dystrophism, etc., to anangioplasic infantilism. The dysthyroid etiologic unity of infantilism is proved: 1, by the existence in the same family of different types of infantilism; 2, by dysthyroid antecedents on the part of the parents; 3, by the

therapeutic effect of the administration of thyroid product on these different forms of infantilism (*Presse Méd.*, March 9). S. Goldberg also proclaims in the *St. P. Med. Wch.*, March 26, as the results of extensive experimental work and observation, the close connection between dysthyroidism and trophic disturbances in the growth of the young.

Diversity of Action of Antipyretics.—Among the conclusions resulting from a recent comprehensive investigation of the antipyretics, we notice that the hypothermic action of most of the convulsion-producing poisons is due to the excitation of the nerve-centers that arrest the thermogenesis. Anesthetics on the other hand act by paralyzing the thermogenetic centers, and have no effect upon the arresting centers.—*Presse Méd.*, March 9.

Isolated Aphasia as a Premonitory Symptom of Uremic Attacks is very rare. Rose adds another to the two cases on record. The patient had chronic parenchymatous nephritis, under apparent control with milk diet and digitalis. Suddenly acute isolated aphasia developed, followed in a short while with a violent uremic attack, lasting nearly twenty-four hours with loss of consciousness, etc. The aphasia passed away with the attack. He is inclined to ascribe it to auto-intoxication, as the anatomic position and the angular course of "Carnot's apoplectic artery" render it especially liable to be affected by increased pressure in the circulation.—*Gazzetta degli Osp. e delle Clin.*, March 17.

Production of a Mucinoid Substance by Bacteria.—Charrin and Desgrez have isolated, from cultures of the pyocyanus, a substance resembling the mucin found in meat bouillon, with a phosphorus reaction in the precipitate, which suggests that the mucinoid substance is accompanied with a nucleo-albumin. The microbial cell therefore produces a substance analogous to that produced by the cells of the organism and a whole series of vegetable cells. It is toxic injected into rabbits. They suggest that the bacteria which flourish so abundantly in the course of muco-membranous inflammation may be a factor in the genesis of the mucous secretions. Lepierre finds that the fluorescent bacillus also produces a similar substance, but without the phosphorus reaction, and with other properties which proclaim it a true mucin. It produces the mucin in a number of media, all mineral and peptonized, but not in meat bouillon.—*Presse Méd.*, March 2, and *Semaine Méd.*, March 16.

The Value of the Blister and Revulsive Measures in general has been the subject of heated discussion at the Paris Académie de Méd. for more than half a dozen recent sessions. The majority still favor them for certain purposes, and numerous instances were cited in which great benefit had been derived, but Huchard maintained that the blister had passed away with the æton, etc., and related cases in which severe ophthalmia had followed its use, adding that the same therapeutic effects could be obtained with less dangerous measures. Ferrand referred to Winternitz's establishment of the fact that irritations of the skin not only induce hyperleucocytosis at the point irritated, but throughout the entire lymphatic system and circulation. He observed that "microbian physiology has proved an evolution of our science rather than a revolution. Facts never die, and the blister is a fact which has seen many generations pass away, and will survive ours."

A Study of the Blind.—Pearce (*Internat. Med. Mag.*, March), gives in an analysis of 180 pupils of the Pennsylvania Institution for the Blind, the following interesting data: Tests for hearing showed a wide range of difference in the acuity of audition between the right and left ear. In the boys the average distance for the left ear was fourteen feet, for the right ear, fifteen feet; in the girls the average for the right ear was thirteen feet, and for the left ear twelve. Forty-six girls, 54 per cent., had constant marked rotation of the eyeball, of which 19

were irregular or nystagmoid, 37 had a less marked slight rotary movement. Five also had nystagmus in the right eye and one in left eye only. In the girls there was no nystagmus. Among the boys 83 per cent. had constant rotary nystagmus, 6 per cent. slight rotary, 6 per cent. lateral alone, and 3 per cent. no nystagmus; 1 per cent. had nystagmus in right eye only and 1 per cent. in left eye only. Of the girls, 58 were partially, 28 totally blind; of the boys, 68 per cent. partially, 32 per cent. totally blind. Specific taint was noted in 6 boys and suspicioned in 6; phthisis diathesis in 28 girls, 33 per cent., and in 13 per cent. of the boys; deformities of the spine in 38 girls and 34 boys. Muscle-jerks were seldom abnormal and skin reflexes were active.

Immunity-Period from Diphtheria Antitoxin.—In the *Boston Medical and Surgical Journal* of March 3, Morrill reports the results of observations in diphtheria immunization as carried out in the Children's Hospital of Boston. Of 1808 patients immunized at least once every twenty-eight days, the amount of serum varying from 150 to 500 units, seven had diphtheria, three from insufficient dosing, two within twenty-four hours of the injection, and two in whom the time of infection came twenty-three and twenty-two days, respectively, after giving an amount which had previously been effective when given every three weeks. Of 829 who were not given antitoxin, or in whom more than twenty-eight days elapsed after the injections, nine had diphtheria, besides three immunized adults. He concludes: 1. That immunity in any given case, of no matter how thorough exposure to diphtheria, may be conferred, for at least ten days, by the injection of a small dose (100-250 units) of serum, provided it is given twenty-four hours previous to actual infection. 2. That a larger dose (250 units for a child of two, up to 500 units for one of eight or over) will confer safety for three weeks, or, to be a little more conservative, twenty days, under similar conditions. 3. That no harm will result from the treatment in a vast majority of cases of sick children, and probably in no case of a healthy child, provided the serum used is up to the present standard of purity.

A New England Worthy: an Early Reformer.—At Wayland, Mass., the tomb of Dr. Hayward exists that shows that there were reformers before the mugwumps. Its epitaph reads:

Here lies the body of Dr. Hayward,
A man who never voted;
Of such is the Kingdom of Heaven.

If we are not mistaken in the identity of the gentleman, he had the advantages of Harvard education and of a walk through the hospitals of London over a century ago. Also, a Reformer in the South.—The following verses from the *British Medical Journal* have the local colors of the bayous and parishes of southern Louisiana. They commemorate the habits of the life of the veteran practitioner, "Ole Docteur Fiset who has got ninety years or so:"

But Docteur Fiset, not moche fonne he get,
Drivin' all over the whole contree:
If de road she's bad, if de road she's good,
When ev'ryt'ing's drown on de Spring-tam flood,
And working for not'ing half time mebbe.

Let her rain or snow, all he want to know
Is jus' if anywan's feelin' sick,
For Docteur Fiset's de ole-fashion kin',
Doin' good was de only t'ing on hees min',
So he got no use for de politique.

Surgical Interference in Cerebral Disease.—In the *N. Y. Medical Journal* for April 16, Fisher gives the following special indications for operation: 1. Fracture of the skull, causing compression with resulting paralysis, epileptic seizures or coma. 2. Meningeal hemorrhages, traumatic or occurring in pachymeningitis hemorrhagica. 3. Tumors of the brain when situated near the cortex of the brain or even in the cerebellum, but not when deeply situated or at the base. When the tumor

is not thought to be a removable one, a partial operation may be indicated, as the removal of a large area of the skull often relieves certain marked symptoms of tumor, as vomiting, headache, and convulsions. 4. Localized epileptic seizures of the so-called Jacksonian type. I would include in this class cases, whether due to injury or arising from unknown causes, that is, so called idiopathic epilepsy, if limited to special parts of the body, as the arm, leg, or face, or all three, if only one side of the body is involved. In such cases I would advise the excision of these cerebral centers. This, indeed, results in paralysis, perhaps a permanent form; but in many of these patients we have already a certain degree of paralysis, and in that case we simply increase a previous disability. 5. Cerebral abscess, and especially in the form most commonly presented to us, that following otitis media. I will not include under this head operations in microcephalia or in infantile cerebral hemiplegia with epilepsy, although in some cases, owing to the otherwise hopeless character of these conditions, I am in favor of operative interference.

Medical Colleges in America from a German Point of View.—Dr. S. Placzek of Berlin reviews, in the *Deu. Med. Woch.*, of March 17, the "Student's Number" of the *JOURNAL*, containing the particulars in regard to the medical colleges throughout the country. He is amazed at the enormous number of such institutions: 148, including the thirteen in Canada, and deplores the low standard for admission that prevails generally, which he states with astonishment, is merely the elementary principles of English, Latin, arithmetic, algebra and physics. He remarks that a number of cities enjoy the luxury of several medical schools at once, allowing them the privilege of amicably competing for students. He appreciates the advance made in late years in lengthening the course in some colleges, but states that it is still too short." A five-year course is none too long. It would certainly abolish the remarkable phenomenon, without parallel of a nineteen-year old physician! But the chief drawback to this plethora of colleges, in his opinion, is the inability to provide trained professors for them all. Institutions of learning can be founded by the "Almighty Dollar," but it is impossible to provide skilled experts to fill all the chairs in these 148 colleges with equal rapidity, even by summoning excellent assistance from Europe, such men as Klebs, van Ackeren, Fehleisen, etc., who happen to be at liberty. In view of this fact "it is not astonishing that out of the entire 148 medical colleges, only eight or ten are to be regarded as of full value." He suggests as a safe-guard against the other 138 that the privilege of conferring the medical diploma should be relegated altogether to a central authority which by its position and the character of its members would afford a guarantee that the privilege would be worthily handled.

Treatment of Urethral Strictures.—Howland (*Medical News*, April 9) writes on "Gradual Dilation Versus Cutting in the Treatment of Urethral Strictures." He says: The best genito-urinary surgeons are now decrying the practice of using the knife at the first sign of a stricture of the urethra. This is good surgery and should be even more generally practiced. Dilation is always advisable and more often successful than surgeons generally believe. The length of period necessary to effect a cure depends largely on the patient and on the stricture, the length of time it has existed, and its location in the urethra, varying from three to twelve months. Many patients prefer the cutting operation to this long treatment, until they understand that with such operations the cure is not as permanent and sounds have to be passed at regular intervals. I have observed the best results from gradual dilation up to and not exceeding 32 French, and if a urethra thus treated can be maintained at a caliber of 28 or 26 French, it is all that will be required. The dilation should be conducted slowly and with great care, and an advancement of more than two sizes at one

sitting not attempted. At the slightest sign of blood oozing the treatment must cease and the irritated membrane treated by instillation or irrigation with some astringent preparation. I have used plain water at 105 to 110 degrees F., one quart at a sitting, with encouraging results. Never allow a patient to pass sounds upon himself. The writer does not believe that all strictures can be cured by gradual dilation, but he does believe that a great number can be.

Gleanings.—The Mexican National Institute of Aerotherapeutics has now a record of 100 patients treated with compressed air, all very much improved, asthma, emphysema, bronchi-ectasia and chronic bronchitis.—*Chronica Med. Mex.*, February 1.—Treatment of soft chancres with a stream of hot air at 42 degrees C. is now being successfully tried by Haramb of Constantinople.—*Ann. de Derm. et de Syph.*, December, 1897.—Fatal hemorrhage from the eyes of day old infant.—*Inqno Russ. Med. Gaz.*, 1898, 2.—Acute affections of lachrymal sac cured in three weeks with massage.—*Wien. Med. Jour.*, 1897, 7.—Two cases of diabetes remarkably improved with methyl blue.—*Bull. Gén. de Therap.*, January 15.—A case of glanders located in the lachrymal gland, differentiated by bacterial examination.—*Rev. Méd. de la Suisse*, December, 1897.—Unique fatal case of hepatic complications in measles with rupture of the diaphragm.—*Gazz. d. Osp. e d. Clin.* Nov. 23, 1897.—Success of large doses of pilocarpin in arresting and curing severe cases of croupous laryngitis and pneumonia.—*Wien. Med. Woch.*, 1897, 27.—E. Doyen has now a record of fifty successes in fifty-five cases of non-cancerous affections of the stomach operated.—Boric acid the only antiseptic for hemorrhoids, chiefly on account of its analgesic properties.—Normal pregnancy and delivery in women nephrectomized on the right side two years previously for lithopyonephrosis.—*Revue de Chir.*, March 10.—Twelve cases of tuberculosis of the bones of the skull. All except two involved the frontal bone. Usually several foci. Course mild and frequently terminated in recovery. No cases of connected meningitis observed.—*Cbl. f. Chir.*, March 12.—Classic lesions of tabes and poliomyelitis found at necropsy of case of chronic saturnine intoxication. No syphilitic antecedents.—*Wien. Med. Woch.*, 1897, 18.—Remarkable success of itrol (arg. citric. pur.) in forty cases of venereal ulcers, including several with gangrene, reported by O. Werler.—*Memorabilien*, March 14.

Litholapaxy in India; A Series of 400 Operations.—Dr. Richard Baker, formerly civil surgeon at Hyderabad, Scinde, has published, in the London *Lancet*, 204 additional cases of litholapaxy, making over 400 cases in his service in India. His earlier series of 200 cases was reported by him in the same journal, for October 10, 1896. The mortality was limited to one death in last reported set of cases, or about one-half of 1 per cent. The fatal case occurred after sixty recoveries, and it was followed by 140 consecutive recoveries; this, the author says, is "nothing very unusual" for the surgery of India where the operation has graduated from the position of being still under trial. These 404 cases furnish another example of the remarkable low mortality which attends the operation of Bigelow as it is practiced in India by British surgeons upon native patients, it being in his last series 0.49 per cent. The cases are tabulated and summarized as follows: Mussulmans, 168; Hindoos, 36; males, 200; females, 4; ages under one year, 1; one to three years, 65; six to ten years, 36; eleven to fifteen years, 4; sixteen to forty-five years, 53; forty-six to fifty-five years, 28; forty-eight to sixty-five years, 13; over sixty-five years, 6; average duration of operation, twelve minutes, nineteen seconds; average weight of stone, 2 drams, 46 grains; average stay in hospital, little under two days. Regarding the strikingly successful results of this operation in the hands of surgeons in India, it has been suggested that they are probably to be re-

ferred to the enormous number of cases of stone which occur in that country as compared with others, and the greater technic dexterity gained thereby by the operators, and possibly also to some exceptional aptitude on the part of the native to withstand surgical operations. The same proportion of success has not been, and can not be expected to be reached elsewhere.

Dr. Holmes' Examinations in Anatomy.—Prof. William James of Harvard University is a M.D. of the class of 1886, but is a psychologist and not a practitioner. He has a very distinct recollection of the anatomic part of his examination. When he came before the genial Dr. Oliver Wendell Holmes, the latter asked him some questions about the nerves at the base of the brain. It so happened that the examinee was well up on that subject and he gave a pretty exhaustive reply. "Oh, well, if you know that you know everything," said Dr. Holmes, cheerfully, "let's talk about something else. How are all your people at home?" "In that pleasant way," says Dr. James, "I completed my examination in that subject. I do not remember having encountered any difficulties in any of the subjects. The examination for the degree was oral and lasted just an hour and a half. These ninety minutes were equally divided among nine subjects, ten minutes to each. Each of us as he came in took a seat at a desk, behind which stood the professor who was to conduct the examination in that particular subject. The professor asked the questions and we answered them as best we could. Out in the hall stood the janitor beside the big gong, and at the expiration of the ten minutes he pounded the big gong. This was the signal for all the students to get up and change desks, much after manner of your progressive eucher parties. There were two other matters to be attended to before I got my M.D. I had to write a thesis, and I did it. Then I went to the dispensary and took a case for diagnosis and treatment. There was a lump on the back of the man's neck which I diagnosed as a carbuncle, and for which I prescribed hot poultices. It was with feelings of apprehension that I learned later that the patient was suffering from an internal disorder, and the test was on that. However, the examining board were very kind about it. They admitted that my course in diagnosing the first trouble I came across in my patient, namely, the carbuncle, which was plainly apparent to the examiner's eye, was quite natural, and said that my treatment was the proper one. Therefore, I was adjudged satisfactory.

Results in 100 Abdominal Operations.—Shoemaker (*Phila. Med. Journal*, March 26) gives the results of an investigation in a consecutive group of celiotomy cases of various sorts, all the cases being women with gynecologic disorders. Of the 100 cases, 6 died; 2 cases of hysterectomy for fibromata weighing fifteen and one-half and seven and one-half pounds respectively; 1 case of extra-uterine fetation, septic when first seen; one following removal of ovaries in intraligamentary fibroid tumor of uterus, adhesive to pelvis; 1 following removal in severe double gonorrheal pyosalpinx with bowel adhesions, and 1, unexpected, following removal of one diseased ovary and tube and suspension of retroverted uterus. Hysterectomy was done 19 times. In the series 3 were malignant, 8 fibromas, 1 a fibrocyst in an extra-uterine case, 7 were for hopeless inflammatory disease of uterus, tubes and ovaries. He believes that "the uterus is better removed when itself diseased, if large, heavy and retroverted, with poor support, when it has been for years the channel for outpour for chronic discharges, when hemorrhage has been excessive from glandular degeneration of the endometrium. This is especially true in elderly multiparæ. The risks of removal are not great." He, however, is opposed to removal of normal ovaries for nervous conditions, believing in correction of the disease causing the persistent irritation or hemorrhage, as a means of relieving the nervous condition. Thirty-

nine cases with gross anatomic lesions showed marked nervous disturbance and 77 per cent. are cured or markedly improved. In numbers of cases, marked hysteric or other nervous disturbance proved to be only a surface-play of symptoms, while serious pelvic disease had been one of a chain of causes. Hernia in operation wounds occurred six times, in one case a woman, operated on when four months pregnant, who went safely through delivery at term, the hernia occurring nineteen months later. Inflammatory disease of tubes and ovaries, requiring removal, occurred 35 times, extra-uterine pregnancy was present 5 times, cystic tumors of the ovaries 7 times; in 1 case there was a large dermoid; broad-ligament cysts were present 3 times; 5 cases had abdominal tuberculosis. Uterine suspension was done but once as an independent operation for severe symptoms due to retroversion and descent of the uterus. This patient was cured permanently and has remained well more than two years after ten years of suffering. Of the 94 cases surviving operation, 49 (59 per cent. of the cases heard from) are cured after a period of from six months to two years; 32 are improved, though 14 of these are anatomically cured; 4 of the 5 tuberculous cases were improved and 1 cured. The most satisfactory results were in the large tumor cases, then the chronic pus cases in which there was 1 death in 22 cases. He concludes: "As to benign tumors, there are none involving uterus, tubes and ovaries that can not, at the present day, be removed with a comparatively low mortality, depending upon the stage at which the case is seen and upon the skill and experience of the operator in abdominal work, on his surgical judgment and on the organization of assistants and plant, with the aid of which he operates. Very much depends upon good detail work. By the modern steam sterilizer the last excuse for a septic death has been removed. Even the stitch-hole abscess should be the rarest of exceptions and call for rigid explanation."
